This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

**Usage guidelines**

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

**About Google Book Search**

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

### ARTERIAL SCLEROSIS AS A CAUSE OF NERVOUS DISEASE.

BY M. ALLEN STARR, M.D., LL.D.,

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

I. THE rôle that is played in the etiology of nervous diseases by endarteritis is becoming more and more widely recognized. It has, of course, long been known that disease of the arteries is the primary affection in the ordinary type of hemiplegia; whether due to a rupture of the vessel and hemorrhage, or to a stoppage of the blood current by thrombosis or embolism. Ever since the classical studies of Heubner upon syphilitic endarteritis this cause has been recognized in those cases of apoplexy which are so common among syphilitics in early life. It is not, however, a matter of general knowledge that a very large number of the cases of hemiplegia occurring in childhood and in infancy are also to be traced to vascular disease. It is true that the infantile hemiplegias are, in many cases, of traumatic origin; injuries at birth producing a rupture of the blood vessels and consequent destruction of the brain tissue, which subsequently prevents its proper development. But there are a large number of cases of infantile hemiplegia that are not traceable to this cause, in which the attack has developed during the first or second year of life, possibly as a sequel to some reflex convulsion and possibly without apparent ascertainable cause. Recent investigations have proven that obliterating endarteritis may be the result of inherited syphilis, and hence it becomes evident that disease of the blood vessels is a factor in the causation of infantile cerebral palsies.

A careful study of two hundred consecutive cases of apoplexy in private practice of which I have records has shown that in 80 per cent. of these cases there have been distinct prodromata of the apoplectic attack. For months, or even years, before the occurrence of the rupture or occlusion of the blood vessel the patients have complained of various symptoms which have usually been designated as neurasthenic. These symptoms all point to a disturbance of function in the brain, chiefly in the cortical activity. The symptoms are very numerous and variable. Those that are the most commonly observed are a disturbance of mental action which the patients complain of as a dulness and hebetude, difficulty of clear thinking, difficulty in remembering events of recent occurrence, a sense of perplexity in regard to matters which should be clear; a sense of difficulty in the management of affairs which should be easy; and an irritability of temper and lack of control over emotions, that become a source of annoyance both to themselves and to the members of their family. Other patients complain of temporary sensations of numbness in one limb, or in one side of the body; of irregular darting pains through the head; of ringing in the ears, or of sounds in the head; of slight uncertainties of vision, occasional sudden dimness being not uncommon, and of vertigo. These symptoms occur with such uniformity as a preliminary to apoplectic attacks that they cannot be considered as merely of neurasthenic origin but must be traced to the malnutrition of the neurones consequent upon the original arterial disease. As all the processes of nutrition in brain cells and fibers must be carried on primarily by a process of osmosis through the vessel walls, it stands to reason that the earliest evidence of disease in these walls will be imperfect function consequent upon malnutrition.

The practical outcome of these observations is to warn the practitioner against dismissing a middle-aged person who complains of these symptoms with the mere diagnosis of neurasthenia. In every such case the condition of the blood vessels should be investigated, attention being paid not merely to the nervous manifestations, but also to the condition of the heart, the possible existence of an accentuated second sound of the heart, the tension of the arteries, not merely in one wrist but in various parts of the body, especially in the temple, and the condition of the kidneys. If these factors be recognized and the condition of arterial sclerosis be made the object of treatment, the so-called neurasthenia will be much more likely to yield to treatment than if attention be merely concentrated upon remedies directed to the nervous system. I do not wish to have it supposed that all cases of neurasthenia have this origin. The large majority of such cases are due to malnutrition and auto-intoxication.[1] But in persons in middle life or beginning old age arterial disease may be a cause.

II. The facts hitherto mentioned are a matter of common knowledge and will be recognized by every physician. It is not as commonly known that the majority of diseases of the spinal cord are equally traceable to disease in the vessel wall. Williamson of Manchester[2] was the first to call attention to this fact; and here and there articles have appeared confirmatory of his position. But even in recent textbooks there is a lack of clear statement of the rôle which arterial sclerosis plays in the production of spinal paralysis. I may mention a few of the diseases in which it enters as an important etiological factor:

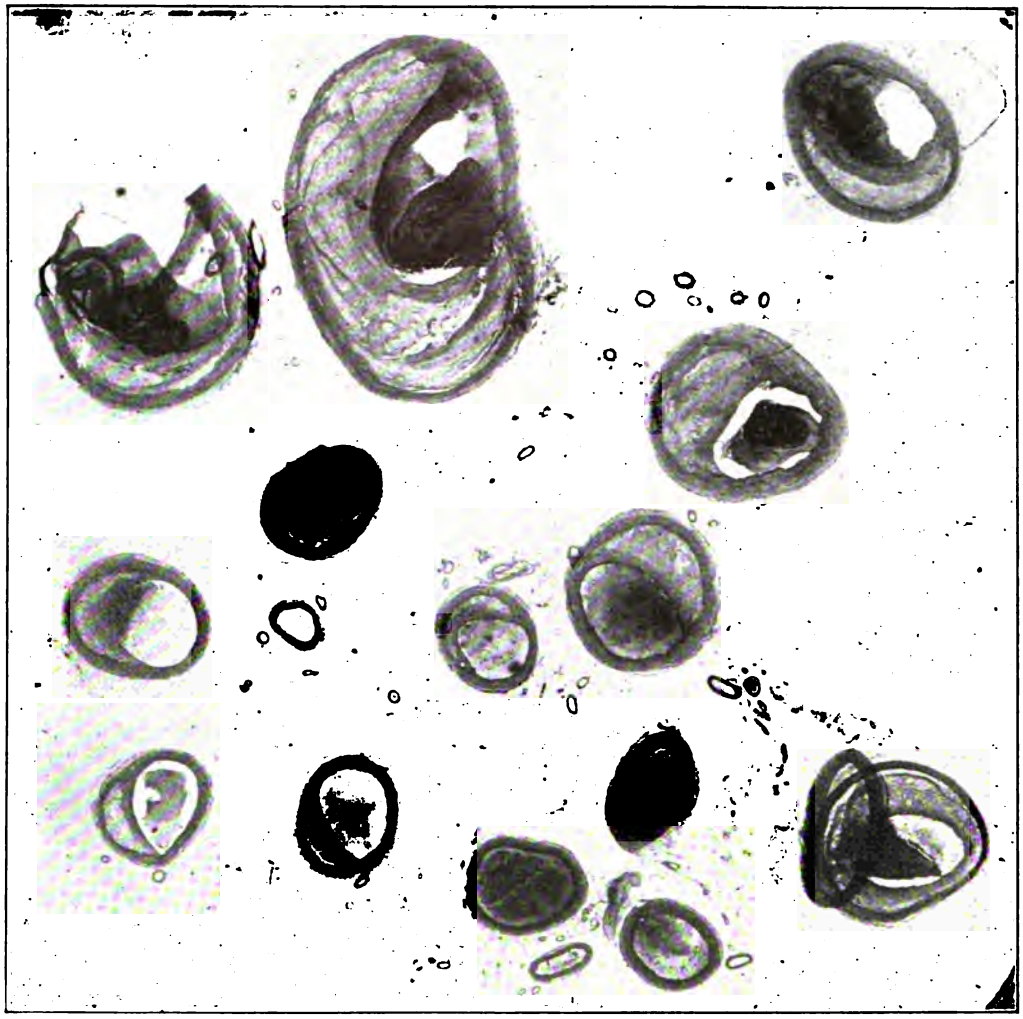
First: Anterior poliomyelitis, bulbar paralysis and ophthalmoplegia, that are diseases of homologous motor neurones of the cord and cerebral axis, are now known to fall into two categories, according to their origin. The majority of the cases are clearly infectious. This is proven in the case of anterior poliomyelitis by the occurrence of the disease in epidemics. But there is quite a proportion of the cases of anterior poliomyelitis which occur without the febrile movement characteristic of infectious disease. Recent pathological observations, especially of Mott,[3] have demonstrated the lesion to be a rupture in some cases, a thrombosis in other cases, of some branch of the anterior spinal artery supplying the anterior gray horns of the spinal cord. And what is true of anterior poliomyelitis has also been found true of bulbar palsy and ophthalmoplegia, for in a number of cases of this affection Siemerling

and others have found vascular disease as the basis of the lesion.

Second: Myelitis whether of disseminated or transverse variety is also traceable either to infection or to a rupture of a blood vessel, in the latter case occurring as does cerebral hemiplegia without febrile symptoms. Investigation of Savage[4] and of Allan have proven the existence of arterial changes in many cases of this disease.

Third: The condition of spastic paralysis commonly known as Erb's syphilitic paraplegia is now recognized as due to malnutrition of the dorsal region of the spinal cord with consequent descending degeneration in the lateral columns.[5] The origin of the malnutrition of the dorsal region of the cord is the syphilitic endarteritis which obliterates the spinal blood vessels, especially on the posterior and lateral surfaces of the cord, and hence produces a state of malnutrition in the white columns. The endarteritis is of the ordinary obliterating type and is clearly of syphilitic origin, though it must be stated that there is no pathological distinction to be made between obliterating endarteritis which is specific and one which is non-specific.

Fourth: There are numerous cases that have been hitherto classed together as senile paraplegia, in which a gradually advancing weakness culminates in a slowly progressing paralysis of the legs with imperfect control of the bladder, and of the rectum, with atrophy of the muscles, and with irregular and indefinite sensory disturbances, chiefly of the nature of numbness and not attended by pain. This condition appearing as a rule after the age of sixty is prone to advance slowly, and finally becomes a complete paraplegia. It has been classed as the feebleness of old age and has been thought to be due to senile atrophy of the neurones, but, as a matter of fact, Dana showed some time ago and recent autopsies have proven that the disease of the nervous system in these cases is traceable to the obliteration of the blood vessels, to the thickening of their walls, and to the consequent malnutrition of the part.



Group of atheromatous arteries (cerebral) seen under a low power. The walls are thickened (endarteritis) and degeneration is present in the thickened areas.

Fifth: Combined sclerosis, which is a comparatively rare but easily recognized form of paraplegia, presenting a combination of the symptoms of spastic paralysis with the unsteady gait of locomotor ataxia, and which was named by Gowers ataxic paraplegia, has been recently shown by Marie[6] to be due to malnutrition of the posterior and lateral columns of the cord consequent upon arterial disease. Marie's specimens show a thickening of the arteries and a degeneration in the cord that follows the distribution of the spinal blood vessels.

Thus we see that many forms of spinal-cord disease can be traced to arterial degeneration.

III. Diseases of the peripheral nerves are also occasionally due to endarteritis in the small vessels which accompany them. It is well known that in cases of chronic alcoholism sudden severe attacks of brachial or sciatic neuritis are observed. These differ from the ordinary alcoholic neuritis in being localized on one side. Some years ago Klumpke saw in one such case an extensive hemorrhage in the posterior cord of the brachial plexus, and described the condition as an apoplectic type of neuritis. Since that observation many others have been published of the same character, and hence we must regard it as probable that in a few cases in which a very sudden onset of either sciatic or brachial neuritis occurs without the ordinary cause of cold, or strain, to explain them, we have to deal with a rupture of a vessel in the nerve trunk. These cases are slow in their course, the symptoms are very intense and last for several weeks, and the case not infrequently becomes a chronic one, owing probably to the formation of a connective tissue scar within the nerve sheath, which constantly produces pressure.

IV. The facts already cited with regard to the occurrence of prodromata in cases of apoplexy traceable to malnutrition in the brain due to arterial disease and mistaken for cerebral neurasthenia, awakens the suspicion that some minor nervous symptoms, both of spinal cord and of nerve disease, may also be due to this same factor. We have a spinal type of neurasthenia characterized by pain in the back, by irregular sensations of numbness and tingling, by irregular pains in the body, twitching of the muscles and feelings of weakness in the limbs, and possibly irregular action of the bladder, and chronic constipation. In these cases it is not sufficient to make the diagnosis of a spinal neurasthenia. Attention must be paid to a possible underlying cause, namely, endarteritis.

V. Various forms of neuralgia may be brought into the same etiological category. It is now well recognized, from the lesions found in the Gasserian ganglion after extirpation for the relief of trigeminal neuralgia, that the origin of neuralgia may be a hemorrhage into the ganglion. Years ago Kaposi showed that hemorrhage into the posterior spinal ganglia was capable of producing both herpes and intercostal neuralgia. Such hemorrhages, of course, imply an affection of the vessel-wall as a predisposing cause, and therefore we are justified in tracing some cases of neuralgia, especially a neuralgia occurring in old age, to arterial degeneration. Dana showed that neuralgia in old persons is often due to sclerosis in the small arteries accompanying the nerve, and applied this fact in the treatment by using nitroglycerin in such cases with success.

I do not wish to be understood as laying too much stress upon this factor in nervous disease. I have no desire to trace *all* nervous affections, including both neurasthenia and serious types of paralysis, to arterial disease, yet I cannot but feel that it is a factor in the production of many forms of nervous disease, and that it should receive more attention in the management of these cases.

And when we consider the forms of treatment which appear to be of most benefit both in neurasthenia, in neuralgias, in spinal paralysis, and in hemiplegia, we find that they include methods which have as a result the establishment of an equable circulation. Thus life in the open air without exposure to great changes of climate; the use of tepid baths of considerable duration, or alternate douches of hot water, long continued, followed by a quick cool douche of short duration; a diet free from alcohol and rich forms of food; moderate exercise, sufficient to produce a mild perspiration, but not sufficient to cause exhaustion and not attended by any great degree of effort; and massage, —are of considerable service.

It has not seemed to me that the ordinary treatment of arterial sclerosis by drugs was very satisfactory. From unknown causes of internal origin a very great variation in the tension of the pulse is commonly observed. Thus a patient with marked degeneration of the arteries will at one time have a very high tension pulse and at another time a soft pulse without high tension. It is, of course, possible by the use of iodide of potassium in 5 or 10-grain doses 3 times a day, or of chloral in 5-grain doses every three hours, of nitroglycerin in varying doses from $\frac{1}{100}$ up to $\frac{1}{50}$ of a grain every three hours, and of nitrite of sodium 1 to 4 grains every three hours, to produce immediate softening in a hard pulse. Yet in a condition in which spontaneous changes in the pulse tension are possible, it is manifestly improper to keep up such remedies constantly. It has seemed to me that there must be some agent within the body which regulates the pulse tension. If that agent is in excess the tension is abnormally low; if that agent is wanting the tension is abnormally high. It has been my observation in the treatment of Basedow's disease that a patient suffering from this condition never has a high-tension pulse. In fact, a low tension is noticeable in this condition.

We cannot but believe that many of the symptoms of Basedow's disease are due to an excess of thyroid secretion in the blood, and it is undoubtedly owing to the presence of this secretion in excess that the low tension of the pulse is due in this affection. This is proven by the therapeutic effects of thyroid extract when administered in myxœdema, or for obesity, or in acromegaly. In all of these diseases I have watched the effect of thyroid extract very carefully, and have uniformly found that it reduced the arterial tension very markedly. It has seemed to me probable, therefore, that in some cases of arterial sclerosis, and in many cases of temporary high-tension pulse, there may be a permanent or temporary defect or arrest of secretion of the thyroid gland. Thus in migraine, in which the sudden attack of sick headache is almost always attended by a very great increase in the arterial tension, there is, as a rule, during the attack a remarkable dryness of the skin, pallor, and coldness of the skin, not unlike that observed in myxœdema. And this is quite suggestive of a sudden arrest of secretion of the thyroid gland as a partial cause of the attack of migraine. But aside from theoretical considerations, which may or may not be correct, the practical effect of the administriation of thyroid extract in conditions of arterial disease is decided. Thus in conditions of temporary high-tension pulse I have found the administration of thyroid extract of very great benefit. And whatever the underlying cause of the increase of arterial tension may be, it is markedly relaxed by the administration of this remedy. Thus in migraine, which has just been mentioned, it is quite capable in many cases of arresting the attack, and in those conditions of vertigo, headache, and confusion of mind which attend a high-tension pulse, and which are associated very often with a lithæmic state, the addition of thyroid extract to other remedies will give marked relief. In conditions of chronic or permanent arterial sclerosis when the pulse tension is constantly high, I have also seen a certain amount

of benefit from its use, and for this reason I much prefer it to the continued use of nitroglycerin.

In this class of patients, especially in those who have suffered organic nervous changes from the effects of the arterial sclerosis, constant, skilful observation appears to be absolutely essential. It is not a difficult matter to instruct a nurse, or some member of the family, in detecting variations in the pulse tension, and even patients themselves soon come to appreciate this with a considerable degree of accuracy. Considering the great normal variations in tension, this is manifestly of importance. For it is useless to give a remedy six days in the week if a high-tension pulse only occurs on the seventh day. In these conditions, therefore, it seems unwise to keep up remedies constantly. It is far better to keep up the skilled observation of the patient and apply the remedy when it is particularly needed. Thus I have one patient who for ten years has had very extensive arterial sclerosis, and who has, about once in eight to ten weeks, without any apparent ascertainable cause, a sudden, quick rise in the arterial tension attended by pressure in the head and a sense of great alarm, and followed in the course of two hours by a general epileptiform convulsion. If in this patient at the time of the beginning of the symptoms nitroglycerin is used freely hypodermically, and chloroform is used by inhalation in moderation, the pulse tension is found to relax and the attack passes off without the onset of the convulsion. There is no object in giving this man a remedy for the relief of tension in the intervals, as at that time his pulse is as soft as possible.

It should never be overlooked that many patients who have extensive arterial disease, atheromatous arteries, and abnormally high-tension pulse, and who show symptoms traceable to these conditions, frequently live to extreme old age, and do not die from the effects of their arterial disease. It should also be remarked that many persons who present evidence of extreme arterial sclerosis live their lives without any symptoms at all. These two facts should be recollected in giving the prognosis in this condition, for however serious the condition may appear during the attack, either of functional or organic nervous disease, we must admit that the underlying condition is one which may spontaneously subside or disappear under treatment.

**A Note on Melanoma.**—C. R. Keyser states that formerly melanomata were always classified as belonging to the sarcomata or connective tissue type of tumors, and microscopically the cells often present a spindle or fusiform shape, and are arranged as in sarcomata; the pigment appears both in and between the cells. But recently it has become more and more patent that all melanotic tumors are not sarcomata, but carcinomata, for the following reasons: (1) An alveolar arrangement of the cells is not at all uncommon. (2) The cells are of an epithelioid type. (3) The tumor originates in the skin, usually in a mole. (4) The lymphatic glands are early affected.—*Medical Times and Hospital Gazette.*

# THE ANATOMY OF PORTAL ANASTOMOSIS.*

By ROLFE FLOYD, M.D.,
NEW YORK.

THIS paper briefly describes: (1) The liver circulation in the fœtus at term; (2) the changes in the liver circulation at birth; (3) the sites of anastomosis between the portal and systemic veins in the adult.

I. The liver circulation in the fœtus at term.—In the fœtus at term the venous capillaries, although already arranged about and in the lobules, as in the adult, do not yet serve to isolate the portal from the systemic veins.

At this time the ***umbilical vein*** (Fig. 1, UM. V.), coursing from the navel in the lower edge of the suspensory ligament, enters the median groove on the under surface of the liver and there gives off small left branches (Fig. 1, L[1]), to the anterior part

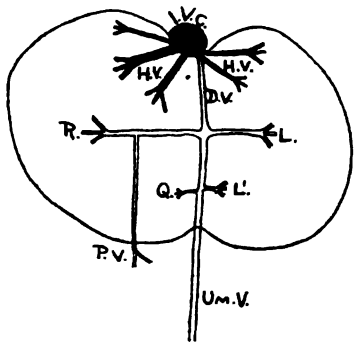

Fig. 1.—Liver circulation prenatal condition. In this and Fig. 2 the liver is viewed from above, the vessels being seen through its substance.

of the left lobe, and small right branches to the quadrate lobe (Fig. 1, Q.). Reaching the left end of the transverse fissure, it ends by dividing into three branches. One, the largest, traverses the transverse fissure and enters the right lobe (Fig. 1, R.), a second passes into the left lobe (Fig. 1, L.) while a third, continuing the direction of the parent stem for about one inch, enters the inferior vena cava, or one of the hepatic veins just before its junction with the cava (Fig. 1, D. V.). This vessel is the ductus venosus, and lies deeply buried in the ductus venosus fissure on the posterior aspect of the liver.

All the branches of the umbilical vein, except the ductus venosus, break up into smaller vessels, which finally end in the capillaries which penetrate the liver lobules.

The *portal vein*, bringing blood from the stomach, intestines, spleen, and pancreas, appears at this time as a comparatively small tributary, which joins the right branch of the umbilical vein where that vessel lies in the transverse fissure of the liver (Fig. 1, P. V.).

The *hepatic veins* (Fig. 1, H. V.) are two or three large vessels on each side, which take origin in the central veins of the lobules, and enter the inferior vena cava just before it perforates the diaphragm.

It is interesting in dissecting these vessels to note that, while the hepatic veins can be exposed by simply rubbing off the friable liver tissue, the branches of the umbilical vein are incased in a firm, connective tissue sheath. In portal obstruction the throttling may quite as well occur in these venules of the portal canals as in the intralobular capillaries.

II. Changes in the liver circulation at birth.—At

*A contribution from the Anatomical Laboratory of the College of Physicians and Surgeons.

birth when the umbilical vein is occluded at the navel, its lumen is obliterated throughout the whole of its extra-hepatic segment, through the proliferation of its inner coat and the formation of a thrombus in the narrowed lumen, which promptly becomes organized. This obliterated segment, from the navel to the liver, now takes the name of the round ligament (Fig. 2, R. L.).

A similar obliteration involves one of its branches, the ductus venosus, although this vessel is still connected with open blood channels at either end (Fig. 2, O. D. V.). It is by the occlusion of this vessel that the portal and systemic veins loose their only large and direct communication and become functionally distinct.

The branches of the umbilical vein, except the ductus venosus, now appear as branches of the portal vein within the liver. The portal vein enlarges considerably with the establishment of digestive processes (Fig. 2, P. V.).

The hepatic veins are in no way altered (Fig. 2, H. V.).

I have found no record of a case of failure of complete closure of the ductus venosus with a secondary

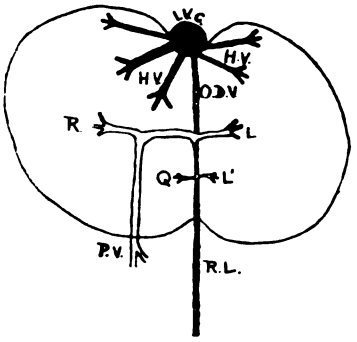

Fig. 2.—Liver circulation, postnatal condition.

enlargement of this vessel in portal obstruction, and, so far as I know, this vessel never supplies a channel of portal anastomosis in the adult.

Concerning the complete obliteration of the lumen of the umbilical vein, there has, however, been some dispute. Sappey, '83, stated that all cases reported as patent umbilical veins, secondarily enlarged and furnishing an anastomotic channel in portal obstruction, were, in truth, not such, but enlarged veins running parallel with the round ligament, and that the latter structure could always be demonstrated in such cases, in its usual adult condition. Baumgarten, '77, however, had stated that with the microscope he had found a

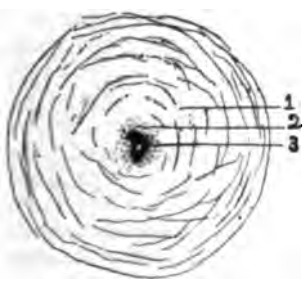

Fig. 3.—Cross section of the round ligament: 1. wall of the original vessel; 2. thickened endothelium of the original vessel; 3. organised thrombus penetrated by vessels.

minute central venous canal in the round ligament in fifty-four cases out of sixty, and that this canal became dilated in portal obstruction. Wertheimer, '86, looking into the matter somewhat more deeply, found that the narrowed lumen of the vein was completely occluded shortly after birth by a plug of connective tissue, and that subsequently, within a year or two, in the majority of his cases, nine out of sixteen, a venule appeared in this central plug (Fig. 3), which communicated with the small veins coursing on the surface of the round ligament. This central venule penetrated the round ligament from its attachment to the abdominal wall to its junction with the still patent region within the liver. This venule was occasionally double, or broken into a fine, venous net. At the same time he reported three cases of portal obstruction, in one of which the

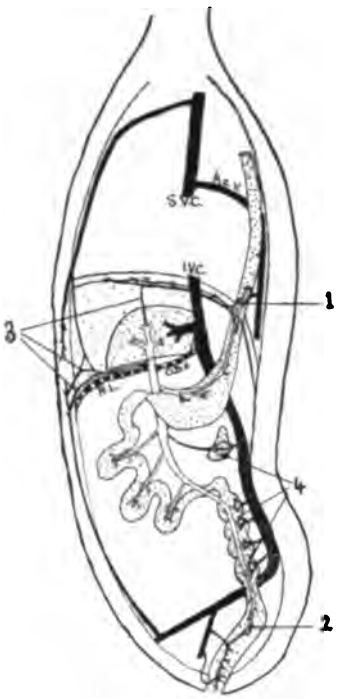

Fig. 4.—Diagram to show the sites of portal anastomosis in the adult; the portal system of veins is shown in outline, the systemic veins in black, the round ligament and ductus venosus in broken line; the viscera are indicated by thick dotting, the suspensory ligament by sparse dotting.

round ligament was not enlarged, and contained no central venule, while in the other two there was a distinct enlargement of the round ligament as a whole, and an increase of the central channel to eight times its usual diameter.

Thus it appears that in some cases, at least, the umbilical vein may be reclaimed, in this roundabout fashion, to its function as a blood vessel, and form a channel of communication between the portal and systemic veins.

III. Normal sites of anastomosis between portal and systemic veins in the adult.—These may be divided into four well-marked groups:

1. Anastomoses at the lower end of the œsophagus. The coronary vein of the stomach receives radicles from the lower end of the œsophagus, which lie chiefly between the mucous and muscular layers of its wall. The same region is also drained by veins which pass to the phrenic veins, and so to the inferior cava, and by veins which unite to form the inferior œsophageal tributaries of the azygos veins and so enter the superior cava (Fig. 4, 1). In the body which I dissected in connection with this paper, the two most evident veins in this region were the coronary vein, and a lower œsophageal vein which passed to the vena azygos major.

2. Rectal anastomosis. The hemorrhoidal venous plexus lies between the muscular and mucous coats

of the rectum. It is drained above by tributaries of the inferior mesenteric vein of the portal system, laterally, by rectal veins which enter the internal iliacs and, below, by the inferior hemorrhoidal veins which pass to the internal pudic veins, and so again to the internal iliacs (Fig. 4, 2). This plexus thus constitutes a pretty free anastomosis between the portal and systemic veins. In the body which I examined, injection mass, thrown into the internal iliac, passed into the inferior mesenteric vein, establishing the fact of the anastomosis in that case beyond question.

3. The accessory portal veins of Sappey. These are veins in the suspensory ligament of the liver, which establish anastomoses between the portal system of the one hand, and the veins of the anterior abdominal wall and of the diaphragm on the other (Fig. 4, 3). Those which pass up to the phrenic veins take origin within the liver substance from small portal branches, not from the portal trunk, and

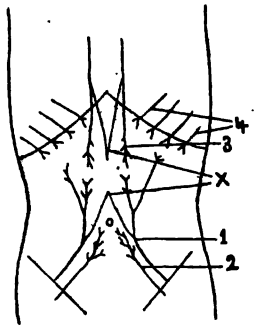

Fig. 5.—Diagram of the veins of the anterior abdominal wall; 1, deep epigastric; 2, superficial epigastric; 3, superior epigastric; 4, intercostal; X, branches from the internal mammary and deep epigastric veins which pass into the suspensory ligament.

emerge from the upper surface of the organ to enter the suspensory ligament. Those which pass forward, on the other hand, root in the portal vein in the transverse fissure. Some of these course along the surface of the round ligament, while others lie higher up in the suspensory ligament. These veins regularly connect with the veins of the anterior abdominal wall. The situation of one of these veins in the center of the round ligament has already been referred to. In the body which I examined they united, while still in the suspensory ligament with vessels derived from the internal mammary, and deep epigastric veins.

In this connection it is worth while enumerating the veins which drain the upper part of the anterior abdominal wall. They are: (1) Deep epigastrics, tributaries of the external iliac; (2) superficial epigastrics, tributaries of the femorals through the saphenous; (3) superior epigastrics, tributaries of the internal mammaries; (4) intercostal veins of the sixth to the ninth spaces, tributaries of the azygos veins (See Fig. 5.). All or any of these channels may be enlarged in portal obstruction. Sappey calls attention to the fact that when the deep epigastric vein is enlarged no varices form, while if the superficial epigastric forms the main channel of anastomosis subcutaneous varices form which may even grow so large as to merit the name of "caput medusæ." He explains this by the angle of confluence in the two cases—the deep epigastric entering the iliac vein at a right angle, while the superficial vessel enters the saphenous vein from above almost directly against the current of blood in that vessel. Perhaps a simpler reason for this difference is that the subcutaneous veins are less supported by pressure from surrounding structures, and so are more liable to become varicose, as is illustrated in the leg so often.

4. The retroperitoneal veins. The duodenum, the pancreas, and part of the colon lie immediately against the posterior abdominal parieties, and, just as in any other continuous mass of tissue in the body, the veins of these viscera, belonging to the portal system, become more or less continuous with the systemic veins of the parieties (Fig. 4, 4.)

In the liver at term, although the capillary system is complete. the portal and systemic veins are not distinct, but become so after birth by the obliteration of the umbilical vein and ductus venosus. The adult anastomoses are the œsophageal, the rectal, the accessory portal veins in the suspensory ligament and the retroperitoneal veins.

---

## SYNOPSIS OF EXPERIMENTS ON THE TRANSFORMATION OF CIRCULATING URIC ACID IN THE ORGANISM OF MAN AND ANIMALS.*

FROM THE HULL PHYSIOLOGICAL LABORATORY OF THE UNIVERSITY OF CHICAGO.

By ALFRED C. CROFTAN, M.D.,

PROFESSOR OF MEDICINE, POST-GRADUATE MEDICAL COLLEGE, CHICAGO.

A COMPLETE report of these experiments will be found in one of the next issues of *Pflüger's Archiv für die gesammte Physiologie, etc.* (Bonn, Germany). In this synopsis I limit myself to reporting the main results of those experiments only that can form the basis of certain clinical conclusions.

*Introductory.*—The general considerations that led up to the experiments to be reported are the following: In a certain congeries of morbid phenomena, variously grouped under the names of gout and goutiness, lithæmia, the uratic diathesis, etc., we find as a constant abnormality the accumulation of uric acid in the blood and tissues. This proposition may fitly be reversed to read that whenever we find a chronic accumulation of uric acid in the blood and tissue juices, and only then, are we justified in speaking of the uratic diathesis. Of the primary cause of goutiness, however, we know absolutely nothing; the uric-acid accumulation is merely one of many symptoms, and that the uric acid *per se* is not the cause of the diathesis I have had occasion repeatedly to emphasize.

The second typical and fairly constant tendency in this diathesis is the formation of concretions of crystalline urates in certain places of predilection. We never find urate concretions unless the uric-acid (urate) content of the blood is previously increased, although we do inversely encounter cases with abnormally large amounts of circulating uric acid in which no urate deposits occur. The factors that determine the formation of these concretions are complicated, only partially understood, and not germane to the subject proper of this article.

As the formation of urate concretions is, however, always secondary to the accumulation of uric acid in the blood, it is clear that any attempt to understand the genesis of these two leading symptoms of the diathesis must be directed primarily toward understanding the factors that produce the accumulation of uric acid; and that any endeavor to treat these symptoms must be concerned with preventing this accumulation or reducing it after it has once occurred.

The accumulation of uric acid in the blood may be imagined to be due to one of three causes, viz., (1) there may be excessive formation of uric acid; (2) there may be retention, scil. deficient elimination of uric acid; (3) there may be deficient de-

*Read before the Chicago Academy of Medicine, February 7, 1903, and the Chicago Pathological Society, March 9, 1903.

struction of uric acid. For it is apparent that uric acid must accumulate (1) if more than normal is formed; (2) if less than normal is eliminated; (3) if less than normal is destroyed. Several of these factors may, of course, be combined.

In this article I treat only of the third possibility. The question to be answered is whether or not uric acid is normally destroyed in the human body. This inquiry settled in the affirmative, we may be justified in postulating that a perversion of this function, *i. e.* deficient destruction, may lead to the accumulation of uric acid in the blood and tissues and hence produce the most characteristic symptoms of goutiness.

It has been known for a long time that uric acid (or urates) administered by mouth to certain animals (dogs, cats, rabbits) appears only in small part in the urine. This by no means signifies, however, that uric acid is destroyed in transit through the animal body proper; for, we may imagine (1) that it is retained in the tissues; (2) that the uric acid is not at all absorbed from the intestine; (3) that it is transformed into other products in the stomach or bowel and that these latter are absorbed. Intravenous injection has furnished more positive results—but here, too, retention, as far as I can read, has never been excluded; nor has it ever been shown that uric acid is not excreted into the bowel (*e. g.* via the liver), thus leaving the body in the fæces instead of the urine.

I have, however, been able to show by the following experiments in rabbits that 80 to 90 per cent. of uric acid that is injected intravenously (*i. e.* of the "circulating" uric acid) actually undergoes intracellular disassimilation; that none of it is retained; and that it is not excreted into the bowel. . .

The method adopted was to inject uric acid in alkaline solution directly into the veins of a rabbit, and to determine the uric acid subsequently voided in the urine. In addition the whole gastrointestinal with its contents and the organs of the animal were examined for any retained uric acid.

As a rabbit excretes only about 5 to 10 c.c. of thick, viscid urine in an hour, and as it is impossible to gather such urine quantitatively by catheterization or in urine cages, it is necessary to stimulate a more abundant flow of urine and to adopt a particular technique in collecting the urine if serious errors are to be avoided.

A very active diuresis may be stimulated by the following solution of salts (S. A. Matthews) injected directly into the veins of the animal:

*m/8 sodium chloride, 50 c.c.; m/24 sodium citrate, 25 c.c.; m/4 sodium sulphate, 23 c.c.; m/8 calcium chloride, 2 c.c.

The urine was collected quantitatively by performing a suprapubic cystotomy and tying a syphon-cannula into the bladder. At the termination of the experiment the bladder (after ligation of ureters and urethra) was dissected out and repeatedly washed with water and the washings united with the urine.

100 c.c. of the salt-solution were first allowed to flow into the vein (at the rate of about 2 c.c. a minute); this stimulates active diuresis (see Table I). In a second portion of 100 c.c. salt-solution, a weighed quantity of uric acid (sodium urate) was dissolved and this mixture allowed to flow into the vein in the same tempo; finally 200 c.c. more of the salt-solution were passed through. The urine was gathered in four portions; portion I consisted of the urine voided during infusion of the first 100 c.c.; portion II of the second 100 c.c.; portion III of the third, and portion IV of the fourth 100 c.c. plus the bladder- and cannula-washings. In each portion the uric acid was determined. Theoretically, nitrogen determinations should have furnished valuable information. As a matter of fact, it was found, however, that much more nitrogen was excreted than corresponded to the uric-acid nitrogen injected. The salt infusion presumably washed out nitrogenous waste products. No conclusions could therefore be drawn from the nitrogen figures, and they are omitted from the table. (See Table I.)

TABLE I.

| Rabbit No. | Uric acid infused | Urine | | | | | | | | Total urine voided | Total uric acid excreted | Loss of uric acid | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Portion I. | | Portion II. | | Portion III. | | Portion IV. | | | | | |
| | | Qty. | U. A. | Qty. | U. A. | Qty. | U. A. | Qty. | U. A. | | | in gr. | in per cent. |
| 1 | 0.26 | 130 c.c. | 0 | 120 | 0.034 | 97 | 0.003 | 104 | 0 | 460 c.c. | 0.037 g. | 0.223 | 83.9 |
| 2 | 0.37 | 127 | 0 | 112 | 0.040 | 102 | 0.001 | 114 | 0 | 455 c.c. | 0.041 g. | 0.329 | 85.8 |
| 3 | 0.52 | 117 | trace | 138 | 0.079 | 88 | 0.011 | 98 | 0 | 441 c.c. | 0.090 g. | 0.430 | 88.9 |
| 4 | 0.46 | 135 | 0 | 109 | 0.069 | 112 | 0.004 | 142 | 0 | 498 c.c. | 0.073 g. | 0.387 | 82.7 |

Some of the animals died during the infusion of the uric acid; this occurs regularly if the uric acid or the urate precipitates from the solution in crystalline form. It is necessary, therefore, to add enough alkali to hold the uric acid in solution.

In animals two and four the blood, organs, and gastrointestinal contents were examined for uric acid according to the method of Stadthagen. The animals were killed by bleeding from the carotid. A ligature was placed around the rectum low down, the œsophagus high up, the bile duct, and the pancreatic duct. The whole gastrointestinal tract with contents was then examined in one portion; in another portion the blood, liver, spleen, kidneys, heart, lungs, brain, shreds of pancreas, the bulk of the muscles and skin were examined. In neither portion could a trace of uric acid be found.

It is demonstrated, therefore, that from 82.7 to 89 per cent. of uric acid infused intravenously to rabbits are actually destroyed (transformed)

*m stands for molecular weight.

within a very short time (one to two hours) in transit through the body of the animal. . . . In human subjects it is more difficult to prove that uric acid is transformed. It has been positively shown† that only a small portion of the uric acid given by mouth is absorbed. Feeding experiments are consequently useless. The intravenous infusion of uric acid and urates cannot be performed for experimental purposes; and subcutaneous injection is hardly a practical procedure, because it is painful and not quite devoid of danger and, chiefly, because retention of the injected uric acid or its elimination through the bowel and subsequent destruction there can never be excluded. Only very small quantities of uric acid could, moreover, be employed for such a test. In man, finally, we know of no characteristic urinary end-products of uric-acid catabolism, as in the case of dogs (allantoin) or rabbits (hippuric acid scil. glycocol). Even the quantitative analysis of the urine would therefore give us little information in regard to the fate of the circulating uric acid.

We are nevertheless justified in assuming, *a priori*, from analogy with animal experiments, that in man the circulating uric acid is actually transformed into other bodies. The only experimental path that is open to us, however, is the investigation of the uric-acid-destroying power of isolated human organs, and this leads us to three inquiries, viz.: (1) Where (in what organs) is uric acid destroyed? (2) How is uric acid destroyed? (3) What becomes of uric acid?

I. *Where (in what organ) Is Uric Acid Destroyed?* A considerable number of investigations have been published on the power of certain animal organs to destroy uric acid.‡

No experiments are recorded with human organs.

The organs were desanguinated, ground to a fine pulp, and allowed to stand under 5 vol. of 95 per cent. alcohol for 24 hours. The alcohol was removed by filtration, the residue washed with ether, spread on filter paper, and allowed to dry in the air; the dry residue was powdered in a mortar and the strands of connective tissue removed by sieving; the powder was finally extracted for twenty-four hours at 37.5° with water containing 2 pro mille of sodium fluoride. Twenty g. of the dry coagulate were extracted with 150 c.c. of water.

These extracts were mixed with uric-acid solutions prepared as follows: One g. of uric acid was suspended in 1,000 c.c. of boiling water, and so much of powdered sodium carbonate added that the uric acid was all dissolved, and remained in solution after cooling. Of this urate solution exactly 300 c.c. (containing approximately 0.33 g. of uric acid) were poured into three flasks, and 100 c.c. of the above extract added to each. In flask I the uric acid was determined at once. The contents of flask II was rapidly carried to the boiling point; the contents of flask III was not boiled. Flasks II and III were kept for forty-eight hours at 38° C. and frequently agitated during this time. At the end of forty-eight hours the uric acid was determined in flasks II and III, according to the method of Ludwig, after removal of all proteids by boiling with sodium chloride and acetic acid.

This technique is the only reliable method for determining the actual loss of uric acid; it eliminates all the sources of error pointed out above and whatever loss may occur by bacterial action, oxidation by the air in alkaline solution, prevention of uric-acid precipitation, etc., occurs in all the flasks (if at all) to the same degree. We have, therefore, an absolute control throughout. (See Table II.)

TABLE II

| Class | Animal | Organ. 20 g.+150 c.c. water =100 c.c. extract | Flask I Uric acid determined at once | Flask II Boiled 48 h. at 38° C. Uric acid | Flask II Loss in g. | Flask III Not boiled, 48 h. at 38° C. Uric acid | Flask III Loss in g | Flask III Loss in % |

As will be seen from the table the organs of herbivorous, carnivorous, and omnivorous animals, including man, were subjected to examination. Boiling reduces the uric-acid-destroying powers of these extracts to a minimum. It is shown that in carnivora the uric-acid-destroying power of the liver is very great, that of the kidneys very small, and that in herbivora the reverse is the case. In omnivora, including man, both the liver and the kidneys can destroy much uric acid; whereas, however, in the hog the power of the liver is greater than that of the kidneys, in human subjects the kidneys possess greater power than the liver. In all species the muscles destroy considerable uric acid. The results obtained with spleen and blood are ambiguous; for while both these organs destroy small quantities of uric acid, approximately the same destruction occurs after boiling the extracts made from these organs; as boiled liver, kidney, and muscle-extracts also destroy some uric acid (as compared to the controls) we must either assume that all the organs contain a uric-acid-destroying agent whose power is not inhibited by boiling (in addition to one whose power is so destroyed), or that the small loss is due to technical errors that are unavoidably committed in all the determinations; in the latter case we would have to deny any uric-acid-destroying power to the blood and the spleen of all species. I am inclined to favor the former supposition.

Wiener (*l. c.*) and Jacoby† were the first to call attention to the peculiar differences existing in regard to uric-acid-destroying power between the liver and the kidneys of herbivorous and carnivorous animals; as these investigators worked with fresh watery extracts throughout, the correspondence between their results and mine demonstrates that the extracts prepared by me by the alcohol method contain the active agent sought; this is an important demonstration, as I will show below, when discussing the finer mechanism of uric-acid transformation.

Philogenetically these differences between herbivora and carnivora may be easily explained as follows: A carnivorous animal eats a large quantity

†Ibrahim und Soetbeer, *Zeitschrift f. phys. Chem.* Vol. XXXV, Heft 1.

‡A complete review of this literature will be found in Burian and Schur. (*Pflüger Archiv.*, Vol. LXXXVII.)

†Jacoby, *Virchow's Archiv*, vol. CLVII.

of food containing much uric-acid-forming material, at long intervals, while an herbivorous animal eats small quantities of food, containing very little uric-acid-forming material, at short intervals. In the former species there is consequently danger of flooding the organism with uric acid and its poisonous congeners at each feeding; this tendency the liver counteracts by its great uric-acid-destroying power. In herbivora no such disintoxicating organ is required to stand between the intestine and the systemic circulation; consequently the chief uric-acid-transforming power is relegated to other organs. The total uric-acid-destroying power of both species may nevertheless be assumed to be the same; there is merely a difference in the distribution of this labor. In omnivorous animals, in accordance with the mixed character of the diet and, in man, in accordance with the regularity of feeding, the uric-acid-destroying function is fairly evenly distributed between liver and kidneys (whenever, however, an excess of uric-acid-forming pabulum is ingested we can imagine that the protective action of the liver becomes inadequate and the system is flooded with abnormal uric acid and the other products of nuclein catabolism that should normally undergo disassimilation in the liver). These differences between the species may possibly be utilized to solve certain mooted problems in the evolution of species.

In interpreting the results chronicled in Table III one must remember that the figures indicate merely the relative uric-acid-destroying powers of the same mass of different organs in the different animals. In order to gain a clear insight into the relative uric-acid-destroying powers of the different organs in each animal it is necessary to compute the relative mass of the different organs as compared to the mass of the animal. Thus we may find, *e. g.* that in a dog a certain weight of muscle-coagulate destroys 8.2 per cent. of uric acid, whereas the same weight of liver-coagulate destroys 31.1 per cent., we may say, therefore, that bulk for bulk the liver of a dog possesses greater uric-acid-destroying powers than the muscles; but when we compute how much more muscle tissue is contained in a dog than liver tissue we will find that in their totality the muscles destroy as much if not more uric acid than the whole liver. The same applies to all the other animals; and while we can only estimate the total muscle weight, I am inclined to attribute to the muscles of all animals and of man the greatest total uric-acid power of all.

The clinical conclusions that can be drawn from these results in human subjects will be summarized in the last paragraphs of this article.

2. *How Is Uric Acid Destroyed?* As all the specific end-products of uric-acid metabolism that have so far been identified are higher oxidation products it seemed probable that the process of uric-acid destruction constituted a process of oxidation. It would lead us too far were we to enter into the theories of intracellular oxidation in this article and I content myself therefore with briefly chronicling the main experimental results obtained in support of the view that uric acid is normally destroyed by oxidation.

The watery extracts of all the organs examined possess the power to a very marked degree of dissociating peroxide of hydrogen and liberating oxygen. If the watery extracts are treated with 5 vol. of 95 per cent. alcohol a white flocculent precipitate forms that in its turn possesses this power. This precipitate is insoluble in water, but readily soluble in a fresh portion of extract; it is also soluble in dilute alkalies. All the solutions possessed marked catalytic power. From the alkaline solution the precipitate could be reclaimed by precipitation with dilute acids; the precipitate contained phosphorus and iron. All these properties rendered it probable that it was a nucleo-proteid, probably identical with the nucleo-proteid discovered by Spitzer in many organs. (See *Pflüger's Archiv*, Vol. LXVII).

In order to determine whether this nucleo-proteid was the uric-acid-destroying agent, a large quantity was prepared from the original extract by precipitation with dilute ($\frac{1}{10}$ normal) acid, according to the method recommended by Spitzer. The precipitate was filtered off, redissolved in dilute ($\frac{1}{10}$ normal) alkali and mixed with a urate solution. Not a trace of uric acid was destroyed after forty-eight hours at 38° C.

In the belief that possibly the solution was too alkaline, a new portion of the nucleo-proteid was dissolved in a fresh portion of the original extract that had been rendered inactive by boiling; this solution, while highly catalytic, could destroy no uric acid. *The nucleo-proteid was not therefore the active agent.*

The "ferment" was next sought for in the solution from which the nucleo-proteid had been removed by filtration. This filtrate was neutralized and mixed with urate solution. No loss of uric acid occurred after forty-eight hours at 38° C. The filtrate contained an albuminoid body that could be precipitated by 5 vol. of 95 per cent. alcohol and that was readily soluble in water; it was not catalytic; it contained neither phosphorus nor iron and was characterized chemically as an albumose; it was present in very much smaller quantities in the extract than the nucleo-proteid.

As neither the nucleo-proteid nor the albumose singly possessed the power to destroy uric acid, and as the original extract that contained these two bodies in solution did possess this power, I attempted to reconstruct the original extract by dissolving the nucleo-proteid and the albumose separately in the (inert) salt-solution prepared from a fresh quantity of the extract as described above. This mixture, it was found, destroyed uric acid in approximately the same proportion as the organ extract from which it had originally been prepared.

The uric-acid-destroying agent in the watery extracts prepared from alcohol coagulates of different organs must therefore be imagined to consist of three substances, viz., (1) a nucleo-proteid with the power to disassociate peroxide of hydrogen, (2) an albumose that does not possess this power, (3) certain salts to hold the nucleo-proteid in solution. The specific agent is apparently the albumose, for the nucleo-proteid is universally present even in those organs that do not possess the power to destroy uric acid. That the salts in the extract are needed to dissolve the nucleo-proteid can be shown by first extracting some of the coagulate with water; a certain amount of nucleo-proteid will go into solution; it is impossible to extract more of the latter by plain water; if the first extract is, however, boiled (to destroy the catalytic action of the extract), and this boiled solution is used to extract the residue of the coagulate, more nucleo-proteid can be extracted without difficulty, the resulting solution again becoming highly catalytic.

Without recurring to extended speculation, I venture the hypothesis that the albumose-like body loosens the affinities of the uric-acid molecule, and that the nucleo-proteid acting as an oxygen-carrier facilitates the subsequent oxidation. (For the experimental basis of this view I refer to a paper on "Intracellular Oxidations" that I will soon publish, and in which the rôle of the oxidases,

peroxidases, and catalases of human organs will be elucidated).

One other point of clinical importance and of direct bearing on the subject under discussion may be mentioned in this place. In studying the effect of various salt-solutions on the catalytic action of the nucleo-proteid and of the watery extracts it was found that certain salts (*e. g.* nitrates and cyanates) greatly diminished the power of the nucleo-proteid to liberate oxygen from a given quantity of peroxide, whereas certain other salts (*e. g.* dilute alkalies and salicylates) greatly increased this power. It is interesting to note this peculiar action of the latter salts in particular. As salicylates and alkalies are the most popular empiric drugs employed in the treatment of the uric-acid diathesis, we are possibly justified, on the bases of these experiments, in postulating that the good effects of these remedies can be attributed to their power to stimulate intracellular oxidation and hence to promote the destruction of accumulating uric acid.

3. *What Becomes of Uric Acid?* This part of the problem I have not been able to solve to my complete satisfaction. As it is probable that uric acid undergoes destruction by oxidation, those products in particular had to be sought for that could be generated from uric acid by oxidation outside of the organism. Such products are urea, oxalic acid, with allantoin as an intermediary product. In dogs, in fact, oxalic acid and allantoin have repeatedly been found after the infusion of urates. I therefore examined the human organ extracts after they had been in contact with uric-acid solutions for varying periods of time for allantoin, urea, and oxalic acid.

Here, again, it was necessary to work with controls throughout; for all organs contain some urea, and some of them can form more urea on standing at blood temperature; it was also possible that some of the organ extracts could form oxalic acid from other ingredients than uric acid (*e. g.* glycuronic acid, P. Meyer).

Allantoin I never discovered even in traces (Method of Loewi). A slight increase of the urea could be discovered in the case of human liver and a slight increase of oxalic acid and of urea in the case of the human kidney. Human muscle generated neither urea nor oxalic acid. The small quantities of these bodies found did not correspond to the amount of uric acid lost. We must assume, therefore, either that uric acid is partially converted into still other bodies or that the urea and the oxalic acid that are formed are oxidized further and thus escape detection. The same applies to allantoin, for it, too, may be formed as an intermediary product that at once undergoes further conversion. I am inclined to the latter view; for there is no valid reason why oxidation should stop at any particular stage.

The experimental reply to the query: "What becomes of uric acid?" is not free from ambiguity. The question is highly complex and calls for further investigation with very large quantities of uric-acid solution and very large quantities of organ extract. I content myself with noting the fact that urea and oxalic acid can be formed from uric acid by certain human organs. For the quantitative details and the analytic technique employed I refer to my German article.

*Clinical Conclusions.*—The experimental results obtained in the case of human organs justify the following conclusions:

1. The fact that watery extracts prepared from liver, kidney, muscle, blood, and spleen can all destroy uric acid to varying degrees, and the fact that this power is largely destroyed by boiling, makes it probable that these organs assume a similar function during life, and that this function is carried on by the aid of unorganized soluble "ferments" that the organs secrete.

One might object that these ferments are present in such minute quantities that they cannot be credited with such an important function; but this objection is invalid; the ferments are present in minimal quantities, because they are not intended to be present in large quantities in the organs at any time. When we prepare the extracts we destroy the cells and *force* the ferments into solution. In studying the action of such an extract, moreover, we see only a small portion of the power that would have been expended had the organs remained alive, had the cells remained intact. I can best illustrate my meaning by comparing the action of the ferment extracted from a kilo of yeast cells and the action of a kilo of living yeast cells. The ferment solution will develop less power by far than the living cells, as in the latter new ferment is continuously being formed; in other words, the action of the ferment accumulating during one hour is only a small proportion of the hourly action of the cells. The ferment solutions made from human organs therefore contain only the *remnant of ferment that is not utilized during life.*

2. The proposition that uric acid is normally destroyed in the human organism may, therefore, be considered answered in the affirmative by these experiments, and from analogy with certain animal experiments that have been described. Inadequacy of this function, other things being equal, may well be imagined to be a cause of uric-acid accumulation in the blood and tissues, and secondarily of some of the most typic symptoms of goutiness.

3. Bulk for bulk, the human kidney destroys more uric acid than the liver, the liver more than the muscles, the muscles more than the spleen and the blood. If one includes the relative bulk of these organs, as compared with the bulk of the whole body, in the calculation, it will be found that the muscles destroy most uric acid, next the kidneys, and then the liver, the spleen, and the blood.

4. The fact that the kidneys normally destroy uric acid teaches that great care should be exercised in drawing conclusions from the plus or minus of the urinary uric-acid excretion; the urinary uric acid can no longer be considered an index of the circulating uric acid; it merely represents the algebraic sum of the circulating uric acid and the uric acid destroyed in the kidneys. There is, therefore, always more of circulating uric acid than is indicated by the urinary uric-acid excretion.

As the majority of cases of goutiness begin with renal insufficiency ("latent" nephritis), and as nearly all advanced cases show typical kidney lesions (granular atrophy), the connection between perversions of the uric-acid-destroying powers of the kidneys as the primary event, and the subsequent development of uratic symptoms is apparent—the fact, moreover, that in lead poisoning granular nephritis precedes the development of gouty symptoms (Ebstein, Levison) lends support to this view. My experiments therefore favor the renal theory of gout.

5. Derangement of the liver function has always been considered a prolific cause of the uratic diathesis; the common interpretation being that more uric acid than normal is formed. It seems more probable that the derangement consists in an inability of the liver to destroy either the normal

amount of circulating uric acid or the excess that is so frequently ingested (in the form of uric-acid-forming pabulum) by sufferers from gout.

6. The power of human muscles to destroy uric acid may explain, as Wiener suggests, why exercise often relieves uratic symptoms; the increased flow of blood-carrying uric acid through the muscles leads to greater uric-acid destruction, and must hence act beneficially.

7. The accelerating effect of salicylates and dilute alkalies on the power of one of the uric-acid destroying bodies (the nucleo-proteid) to liberate oxygen aids in explaining the empiric fact that these remedies act beneficially in the uric-acid diathesis.

8. The formation of oxalic acid from uric acid in the human kidney may explain the clinical fact that in gout oxaluria is not infrequent, and that occasionally the appearance of much oxalic acid in the urine is accompanied by a corresponding decrease in the uric acid of the urine.

9. The formation of urea from uric acid demonstrates that uric acid is not a terminal product, but an intermediary product between certain albumins (nucleins) and urea; the old view, slightly modified, is therefore rehabilitated. It is also clear that much that has been written on the so-called urea-uric acid ratio is sheer nonsense.

10. There is much experimental evidence to show that the function of certain organs that destroy uric acid is also to destroy fats and sugars. Inadequacy of this triple function would lead to the accumulation of fat, of sugar, of uric acid. These considerations point to a pathogenetic relationship between a trinity of diseases that we already know to be clinically related, and that are all three characterized by the accumulation in the blood and tissues of certain bodies (fat, dextrose, uric acid) that should normally be destroyed. I refer to obesity, diabetes and the uratic diathesis.

In conclusion, I wish to thank Prof. Jaques Loeb and Prof. Albert P. Mathews for their courtesy in placing the facilities of the Hull Physiological Laboratory of the University of Chicago at my disposal for this research. I also wish to thank Prof. Ludvig Hektoen and Dr. H. Gideon Wells for supplying me with fresh human organs, and Dr. S. A. Matthews for valuable assistance in performing some of the animal experiments.

100 State Street.

## HOW MAY WE CURE POSTERIOR DISPLACEMENT OF THE UTERUS?*

By AUGUSTIN H. GOELET, M.D.,

NEW YORK.

PROFESSOR OF GYNECOLOGY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE, GYNECOLOGIST TO THE METROPOLITAN HOSPITAL FOR WOMEN AND CHILDREN, ETC.

There is no doubt that a great deal of harm results from improper treatment of posterior displacements of the uterus, and that many needless and unsuccessful operations have been done for the same conditions. It is therefore quite evident that their exact nature and cause are not generally appreciated for errors of treatment and unsuitable operations are too numerous to warrant the belief that they are clearly understood by all who attempt to deal with them. Most frequently error arises from a misconception of the causes operating to produce these displacements and a faulty diagnosis of the exact condition which is the maintaining cause. Before they can be intelligently dealt with, a clear appreciation of the true state of things in and about the uterus is essential.

*Read by invitation at the fifth annual meeting of the Tri-State Medical Association of the Carolinas and Virginia, held at Columbia, S. C., 1903.

What supports the uterus normally must first be considered. Which of the supports are most at fault when the organ is displaced must then be determined. The condition of the endometrium and the uterine walls must be ascertained, and finally, the condition of the appendages and of the peritoneal surface of the uterus must be known; as to whether there is or has been a periuterine inflammation resulting in impairment of the function of the appendages or adhesion to the different structures with which the organ comes into contact.

We will take up first the uterine supports. They are:

The *broad ligaments* which stretch across from side to side of the pelvis and include the uterus between them, affording in their normal state very efficient support. They hold the uterus in the center of the pelvis, prevent lateral displacement, and to a moderate degree its descent, and limit the movement of the body of the organ backward or forward.

The *round ligaments* in their normal state maintain a moderate anterior inclination of the body of the uterus and limit its movement in a backward direction to a certain extent.

The *uterosacral ligaments*, more particularly with the vesico-uterine ligaments to a limited extent, maintain a more or less fixed position of the lower segment of the uterus, whereby the neck of the organ is made to retain a position at right angle to the superior plane or brim of the pelvis. They exert also a very decided influence in preventing descent of the organ.

The integrity of the pelvic floor and of the vaginal walls is also very essential to a correct position of the uterus; hence these structures are likewise to be regarded as supports of that organ.

There is but one set of these supports that maintain anything like a fixed position of that part of the sacral ligaments. Hence a deviation from their organ to which they are attached, viz., the utero-normal state is most important in dealing with displacements of the uterus, posterior displacements in particular.

Both in the non-surgical and in the surgical treatment of these displacements the importance of the uterosacral ligaments is constantly lost sight of. For instance, when the ordinary retroversion pessary is introduced into the vagina to rectify a retroversion of the uterus, if it corrects the displacement it stretches and still further lengthens these ligaments, and therefore tends to retard rather than facilitate a cure. For retroversion of the uterus is possible only when there is relaxation with lengthening of these ligaments. Also when the round ligaments are shortened with the intention of curing a retroversion it fails because the loss of support of the uterosacral ligaments is not taken into account and is not remedied, and the uterus sags down in the pelvis though its fundus may be held forward by the shortened round ligaments.

Very often also the treatment of these posterior displacements is undertaken and the condition of the endometrium and uterine walls is disregarded and injuries to the pelvic floor are not repaired. For instance, it is by no means unusual that a pessary is inserted, and no other treatment is instituted except, perhaps, tampons with glycerin, which is practically useless under such circumstances.

The misconception of the adaptability of certain operative procedures is not an infrequent error. For instance, shortening of the round ligaments when the fundus is attached by adhesions or bands to the rectum, which is pulled forward with it, or when the appendages are enveloped in adhesions—a condition that is more certainly the cause of discomfort than the malposition of the uterus.

A limited number of these posterior displacements of the uterus, both versions and flexions, may be cured without resort to such operations as shortening the round ligaments or ventral suspension, but that they are ever cured by strictly non-operative treatment I am fully prepared to dispute. For in every case there will be found sufficient reason for dilatation of the canal of the cervix with curettage of the endometrium or for inserting a drainage stem to rectify the condition of the uterine walls, and it is not possible otherwise to effect a cure.

Just what procedure should be adopted in individual cases is largely a matter of experience, and it is difficult to outline, except in a general way, what particular class of cases require one method of treatment and which another.

Retroflexions not of too long standing and not adherent may sometimes be cured by instituting as an initial step dilatation of the canal with curettage of the uterus, and then introducing a drainage stem to straighten and change the condition of the uterine walls, which maintain the posterior inclination of the fundus. It is essential, however, that the stem be retained in the canal long enough to bring about a softening of the uterine walls, and during this time the fundus must be thrown forward by a properly adjusted tampon in the vagina. This tampon of absorbent gauze to promote drainage should be repeatedly renewed and readjusted, and the stem must be removed and cleansed from time to time to maintain drainage from the uterine cavity. The cavity should also be cleansed by irrigation when the stem is removed. It will be sufficient in most cases if this stem is retained for a week, and during this time the patient must be confined to bed. When it is removed a pessary is adjusted to hold the fundus in an exaggerated anterior position, and this is retained until there is no longer any tendency of the uterus to bend backward. The pessary and vagina should, of course, be kept clean by frequent irrigation with some alkaline antiseptic, but astringent solutions should not be used, because they favor the formation of encrustation upon the pessary. I use, for this purpose, the liquid synol soap. Should pregnancy occur, permanent cure of the displacement is, as a rule, assured if the patient is properly cared for during puerperal convalescence.

The proportion of cases that are amenable to this method of treatment is very limited. Success more often results in recent cases when involution of the organ is incomplete, and when there is no relaxation of the uterosacral ligaments with complicating retroversion, because when the flexion has been overcome the organ with its cervix occupies a normal position in the pelvis.

When the retroflexed uterus is also retroverted, the best plan is, after overcoming the flexion as described above, to shorten the uterosacral ligaments. In some of these cases, however, a ventral suspension will be required.

In a definite number of movable retroflexions of the uterus uncomplicated by retroversion, a cure is more certainly brought about by shortening the round ligaments, and I prefer to shorten these ligaments in the inguinal canal by the plan described by Kellogg. This procedure is appropriate, however, only in uncomplicated retroflexion. Much discredit has been brought upon this operation by misapplying it and by executing it improperly. As done by its originator, and those who have followed him accurately, it is an ideal operation in appropriate cases. I cannot approve of opening the abdomen to shorten the round ligaments. When that is necessary it is better to do a ventral suspension.

Retroversion of the uterus is a very different problem. Here we have relaxation, with lengthening of the uterosacral ligaments permitting the cervix to occupy a position under the pubes with the uterus at right angle to the vulva orifice, its fundus resting in the hollow of the sacrum. As a rule, the organ is enlarged from metritis and endometritis, which must be overcome before we can hope to effect a cure by any method adapted to hold the uterus in position. It is manifestly unreasonable in such a case to expect a cure to result from the introduction of a pessary, even if it holds the uterus in an anterior position. It is also a mistake to expect a cure from shortening the round ligaments, even if measures are adopted at the same time to overcome the associated metritis and endometritis.

If the uterosacral ligaments have not entirely lost their tonicity and power to retract, a cure may sometimes be effected in these cases by instituting, as an initial step, curettage, with, when necessary, gauze packing of the uterus, to overcome the metritis and endometritis, and afterward supporting the uterus in position by carefully adjusted tampons rather than by a pessary. There is but one form of pessary that is suitable in these cases, viz., a long pessary of the Albert Smith pattern, with its upper part bent over forward so it will rest in front of the cervix instead of behind it. Such a pessary will hold the cervix backward in position, without pressing upon or stretching the uterosacral ligaments. Stimulating applications of faradic electricity are of material benefit in these cases by restoring the tone and aiding retraction of the uterosacral ligaments. This plan of treatment is necessarily tedious, and must extend over a long period. It is applicable to only a limited number of these cases of retroversion of the uterus.

A short time since it occurred to me that the cervix could be retained in a posterior position in these cases by denuding a small area on the posterior surface of the vaginal portion of the cervix and a corresponding place on the vaginal wall in the posterior cul-de-sac of the vagina, and uniting these two denuded surfaces by suture. When the vagina is firmly attached to the rectum, and there is not too much relaxation of the wall, this simple procedure may suffice to hold the cervix backward in position and the fundus would then be thrown forward. As yet, however, I have not given it sufficient test to prove its practical utility.

In a large number of cases of retroversion, a cure is accomplished more satisfactorily by shortening the uterosacral ligaments by the plan advocated by Bovée. In suitable cases it is successful when properly carried out.

If the retroverted uterus is also prolapsed to a considerable degree, and there is a cystocele, I believe a cure is more certainly obtained by ventral suspension. This not only holds the fundus forward, but also draws up the anterior vaginal wall, which is prolapsed. In some cases, however, an anterior colporrhaphy will be necessary also to overcome the cystocele.

When the posteriorly displaced uterus is fixed by adhesion to the rectum, or its movement is limited by adhesive bands so it cannot be replaced, or when the displacement is further complicated by disease of the appendages, there is, to my mind, no more certain means of cure than to open the abdomen, free the fundus, and bring it forward and attach it to the anterior abdominal wall by the method known as ventral suspension (not ventral fixation, a procedure which should be condemned). At the same time, any work found necessary on the appendages is done before the attachment is made. This can

all be done through a small median incision of not more than two inches in length, and in the hands of a careful, painstaking surgeon the operation has no mortality. With care in closing the wound, there is positively no risk of hernia and no disfiguring scar.

It has not been my experience that this operation proves a barrier to pregnancy or labor. When properly done, the result is not a uterus fixed immovably to the abdominal wall, but it swings in an easy, anterior position, and occupies very much the same position as when the round ligaments have been shortened. I have had several cases complete labor at term within a year after operation without complication.

1030 BROADWAY.

## TENT LIFE FOR CONSUMPTIVES.

BY J. EDWARD STUBBERT, M.D.,
NEW YORK.

THE results attained from the climatic treatment of pulmonary tuberculosis have been most encouraging to the medical profession, but not sufficiently so for them to be satisfied with ordering a few weeks' residence for the patient at some popular health resort, accompanied by instructions to remain out of doors several hours a day in favorable weather. The march of progress in the world of medicine is a constant and irresistible movement. Old ideas and theories, based on supposition and belief, must give way to the new and more scientific knowledge founded on pathological study and experimental research. This is illustrated in one way by the history of the evolution in the treatment of tuberculosis. In ancient times it was highly improper to expose a tuberculous patient, especially one beyond the first stage, to a breath of fresh air except on the mildest days in summer, while the night air was dreaded and avoided as the plague. Then the more observant and thoughtful man noticed that those who lived more in the open air did not die as quickly as the hot-house patients, and they began to urge an outdoor life and moderate exercise as a prophylactic as well as a cure for those in the early stages of consumption. Those in the more advanced stages were allowed fresh air only when it was at summer temperature, but even this was better than being kept in-doors in warm, ill-ventilated rooms the whole year. That it was a step in the right direction is shown by the growing tendency among phthisiotherapeutists to have their patients remain out-of-doors the entire twenty-four hours.

I have often had patients tell me, in explaining a rapid disappearance of medicine, "if a teaspoonful is good, a little more must be better, so I took two teaspoonfuls at a dose." I think fresh air the only remedy which would be efficacious in following such logical reasoning. The larger the dose, the better for the patients, but it is often difficult to persuade them to take this view.

There are several plans by which the victim of tuberculosis may continuously breathe pure, fresh air by night as well as by day. Sleeping out in the open air is not harmful to a large majority of tuberculous people, and I have known surprising improvement in all the symptoms as well as a remarkable increase in weight to follow its adoption. I recall the case of a physician, who had consolidation of the right apex with a tendency to hæmoptysis. Tubercle bacilli were present in the sputum. A residence of a few months at Liberty, N. Y., improved his condition slightly, and hæmoptysis was much less frequent until, without warning, he had a chill and a hemorrhage, followed by an afternoon temperature of 101° to 102.5°, which continued with morning remissions for a week. The physical signs during this period indicated an exacerbation of the tuberculous disease, which involved nearly the entire upper lobe. Microscopical examination at this date revealed a greater number of tubercle bacilli than before. At the end of ten days he was prevailed upon to sleep out of doors at night as well as to remain out all day. It was in the fall and the weather moderate when he began this practice, continuing it until February, when he left Liberty apparently cured. A year later, when I examined this patient at my New York office, his condition was even better than when he left Liberty, and I informed him that he might live wherever he desired. He has lived and practised medicine in Virginia for nearly a year and a half.

Millet of Brockton, Mass. (*Maryland Medical Journal*, February, 1901), reports the cases of five patients, whom he recommended to sleep out of doors at night. They were socially of the poorer class and could not incur the expense of a change of climate. They were allowed no roof over their heads except in rainy weather. They wore soft felt hats and cotton night shirts, sleeping under ordinary bedclothes in beds arranged on the roofs of their houses. Remarkable results were observed. Improvement was noted in two weeks. Coughs disappeared, temperatures became normal, respirations were easier, and weight increased rapidly. No attention was paid to dampness and draughts, and heavy dews were regarded as inconvenient simply because of the necessity of drying the bed-clothes. It may be contended that sleeping out of doors in the winter season is not practicable, and that a bedroom with an open window will answer the purpose as well. Experience has taught that such an argument will not stand if put to the test.

Sleeping in a small room with an open window does not appear to be nearly as beneficial to the patient as when the nights are passed on a veranda or in a tent where there is a free circulation of air on all sides. The case of the physician before referred to is only one illustration of this fact. He at first occupied a small, steam-heated room with but one window, and it was never properly ventilated. Improvement in his case was not marked until after his acute exacerbation, when he began sleeping outdoors as well as remaining out all day. If a patient is fortunate enough to have a large room with a southern exposure and containing one or two open fire-places in addition to large windows on three sides, which might be opened widely at night, he might derive approximately the benefit incident to tent life. But comparatively few people can command such a room, and it is the poor people and those in moderate circumstances, living in close, poorly ventilated rooms and apartments, who contribute most heavily to the tuberculous army that we aim to reach. These are the ones, too, who show so markedly the benefit by the great change to open-air sleeping.

There have been reports from widely separated sections of the United States where tent life has been on trial, and the general trend of opinion is decidedly in favor of it. Thus, Stone (*Philadelphia Medical Journal*, October 18, 1902) believes it much better than living in a house in town. He advises using for one patient a tent large enough to accommodate four men. Craig (*Journal of the American Medical Association*, October 4, 1902), as well as Stone, dwells on the climatic conditions which exist in the region of Phoenix, Ariz.; namely, a maximum amount of sunshine, a low degree of humidity, and an equable temperature as most favorable to a continuous outdoor life.

In Pennsylvania the Forestry Commission made

experiments on a State reservation to determine the efficacy of the out-door treatment, and have issued a circular letter in which it is stated that any reputable citizen of the State, who is seeking health, may establish himself on any of the State reservations so long as he violates no law. The Henry Phipps Institute, which is to be erected near Philadelphia, is to be so constructed that every bed can be moved out on a balcony and the patient kept in the open air day and night, if necessary. In the State Institution for Consumptives at Rutland, Mass., the beds are arranged with an extension so that the head of the patient may be projected at night. For this purpose a curtain is dropped from the lower sash of the window about the neck of the patient, ensuring warmth for the body, while with a cap on his head the patient takes the "cure" during his sleep. In case of rain he can raise the curtain, and, without leaving it, roll the bed into the room or ward. This latter method does not seem to be a wise one. It is similar to an arrangement in vogue some time ago whereby the patient was confined to his room, and directed to breathe the fresh air out doors through a tube inserted in the window pane. This foolish plan was soon discarded. It hardly seems any more reasonable to confine the patient's body in one temperature while his head is in another. Guthrie Rankin of London (*British Medical Journal*, January 18, 1902), suggests the possibilities of the open-air treatment in large hospitals, and advocates the establishment of open-air wards in connection with them. He points out that the open-air treatment has not only lowered the mortality, but has convinced him of its curative efficacy.

McGraham of South Carolina suggests placing the patient's bed on a balcony or roof in town, while in the country an arbor or tent is most practicable. He prefers the circular to the army tent, and thinks it better to place it on a platform two feet from the ground, and to do without carpets and draperies.

Tent life should be made as comfortable as possible. Draperies are not necessary, but rugs add greatly to the comfort and convenience of those in ill health, and their use can be made perfectly safe by exposing them to the sunlight for a few hours daily. Fortunately for the patients, the days of cold, cheerless rooms, without a suggestion of home, have passed. No longer is the already forlorn patient denied even the photographs of friends on the wall, nor is he obliged to dress balancing himself on one foot on a bedside rug about the size of a lady's handkerchief.

F. E. Waxham (*Journal of the American Medical Association*, November 29, 1902) points out that tent life should be under medical supervision; and that, in addition to the air, the patient should have food, rest, and comfort; that the strenuous life of a healthy camper should form no part of the invalid life. A. M. Holmes (*New York Medical Journal*, November 29, 1902) is convinced of the greater efficacy of continuous out-of-door life, and urges tent life the year round when the climate permits. C. L. Wheaton (*Indiana Medical Journal*, December, 1902) also testifies to the usefulness of tent life. The majority of trials of tent life have been made in the southwest, where there is the maximum amount of sunshine with the lowest degree of humidity and an equable climate conducive to continuous out-door life. New Mexico, Arizona, and Colorado are most frequently spoken of in this connection. One writer prefers New Mexico and Arizona for the cold months and the region about Denver for the summer season.

A tent sanatorium is soon to be established in Denver, Col., while at Liberty, N. Y., two tent colonies will be open during the summer months under the supervision of the writer and a local physician. One for the richer patients is located on the side of a mountain, which is the highest point between the Great Lakes and New York, and arranged in camps. These camps consist of a living tent that can be made any size desired with as many subdivisions as may be necessary. In the larger room of the tent is located a large stone chimney with an open fireplace to be used in damp weather. One of the smaller compartments is used as a bath and toilet, the sanitary plumbing of which is made perfectly feasible by a main drainage pipe into which all the waste pipes from the different camps lead, and which in turn empties into a meadow at the foot of the mountain. A shanty kitchen is also attached to each camp, and a telephone system connects with the town of Liberty, some two miles distant. These camps are rented by their owner, completely furnished. Being protected on the north by dense forests and flooded by sunshine from the other points of the compass makes the locality an ideal one for camp life. The patients derive all the benefits of a forest without the dampness and exclusion of sunshine.

The other camp is an extension of a boarding house, the proprietor of which rents individual tents for sleeping and living purposes, while all the boarders eat in the common mess-hall of the inn. These tents are intended for patients in moderate circumstances, who desire privacy and yet cannot afford to pay more than $10 per week.

The selection of the style of tent to be used must be governed by the condition and circumstances of the patient. The ideal arrangement would be to have for the summer a wall tent, the sides of which could be elevated day and night, and lowered only to protect the occupant from a driving rain. This forms scarcely more than a sheltering roof and is quite sufficient for the summer months. For the winter, in a cold region, something more substantial is needed, and the conical tent of Gardiner or the wall tent or tent-house of Holmes will answer. Both are constructed with the idea of obtaining the most perfect ventilation in all kinds of weather, it being possible, at the same time, to heat them to 60° or 65° when necessary. This method will ensure the maximum amount of out-door life at all seasons of the year. Tent life in winter, with the temperature hovering about zero or lower, may seem an extremity; and it probably is for advanced or anæmic cases, although even these are made more comfortable and their lives prolonged by such treatment if with it they can have careful nursing and a warm room convenient for toilet purposes. To my mind, lack of proper facilities for toilet and bathing purposes is the only drawback to this treatment for nearly all cases of pulmonary tuberculosis, no matter how far advanced the disease. But the point I wish to emphasize is this, the lives of many persons in the incipient or moderately advanced stages of the disease can be saved by a continuous open-air life the year round. It is true, as has been stated, that such a life is more desirable in a climate like that of Arizona, New Mexico, Colorado, or Southern California, but there are many who must remain at home and, perhaps, even work while receiving treatment. To those who still retain a fair degree of strength, good appetite and digestion, and are possessed of courage and a dauntless determination to get well, the winter tent life, or a necessary home modification of it to fit the purse, is not only possible but desirable. How often do we see the pamphlets of summer hotels at the mountainous resorts frequented by consumptives, stating that those suffering from pulmonary tuberculosis will not be received? Nevertheless, it is not difficult to find them among

the boarders. There is a feeling against the consumptive, and he is not considered a desirable guest. How much better, then, for one to adopt the tent life and receive all of its benefits than to seek hotel hospitality under unfavorable conditions? The foremost of these conditions is the inability to secure a properly ventilated room with easily accessible porches or balconies, where one may remain throughout the day. The self-consciousness of the patient forces him to neglect much of a prescribed treatment rather than attract attention to his condition. The changing, restless life of a hotel is apt to have a depressing effect upon the patient, who is compelled to forego for long periods the pleasures enjoyed by those in health about him. Then, too, certain sanitary precautions cannot be so well observed by the patient. I have patients located in hotels and boarding-houses, as well as isolated in cottages, and I must say that I much prefer those situated as the latter, where the predominating influence of the physician is free from the disconcerting and even harmful suggestions and influences of acquaintances of a day or week. This may seem a small matter, but too frequently have I seen disastrous results follow such hotel life. We should, therefore advocate the erection of tents in connection with hotels in health resorts. This would obviate the refusal to receive consumptive guests by the hotel authorities, and also render it possible for the families of patients to reside near them.

Now, what can we do for the poor people of the cities, who cannot go to the country and hire tents, who can go to very little or no extra expense, and must continue working to maintain their families? For those without domestic responsibilities, who can give up work, there should be provision made by the City or State, and in connection with institutions for this purpose, open-air wards, or some modification by which the patient can obtain sleep out of doors at night, must not be forgotten. For the poor man whose family depends upon his meager earnings, the lot is a hard one. There is sore need of charitable work among the tuberculars of this class. Even while they are often compelled to work under unfavorable conditions, much can be done for them. They can be instructed in hygienic matters, they can be taught the value of fresh air, the other members of the family can be better protected and the earning capacity of the afflicted prolonged. No matter in what climate these sick poor people are found, they need fresh air, and if it cannot be obtained during the day, it should be obtained at night. It occurred to me, even as it did to Millet, that these patients should sleep outdoors at night. In the crowded tenement districts of New York City the roofs of the buildings should be utilized as far as possible. Tents or awnings could be erected, and the patients sleep out not only during the hot summer nights, but far into the cold weather. It is often difficult to persuade the ignorant class that this is a proper proceeding. Indeed, I have sometimes heard professional men object to it, but once the habit is formed and the patient made cognizant of its value by his rapid improvement, it would be easy enough for him to continue it indefinitely and in very cold weather. Example exerts considerable influence among the ignorant classes, and when beneficial results are made apparent to them they are willing to make efforts that will benefit themselves. They may not be able to perceive the benefit of vaccination as a prophylactic of smallpox, but they cannot fail to observe and credit the desirability of the open-air life when they have the example of a sick friend or relative made strong and capable of work by such a course of treatment.

This is a subject worthy of the attention of our wealthy philanthropists, as well as the interests of the members of this society in bringing about a better condition of affairs. If the reporting of pulmonary tuberculosis were compulsory, and it were part of the duty of the sanitary inspectors to see that the sufferers observed certain sanitary measures and were provided with the necessary attention of a physician, who would push the open-air treatment, I believe that it would go a long way toward stamping out the disease. It is a sorrowful fact that New York City to-day is without adequate facilities for the care of the tuberculous poor. Nor, will the building of special hospitals for them be sufficient. Too frequently shall we find it necessary to carry our treatment right into their homes if we are to accomplish our aim.

Finally, a great value of open-air treatment is its cheapness combined with its demonstrated efficacy. It can be arranged for all classes in nearly all climates, with more or less comfort and enjoyment, to the patient, according to his financial standing.

The most desirable site for a camp is not in a forest, but on the edge of woodlands where one can have the full benefit of sunshine and free circulation of air, at the same time being within reach of shade on the hot days or protected from the winds that come with the colder weather. During the summer family relations and home life need not be interfered with in following the open-air treatment, and not only will the patient be greatly benefited, but the entire family will thus be healthier and made less susceptible to the attacks of microorganisms.

25 East Forty-fifth Street.

**Whitlow and Cellulitis.**—Stephen Paget says that it is almost impossible in a bad case of whitlow to do without an anæsthetic—a general anæsthetic whenever possible. Incisions should be thorough; it is better to cut a finger almost to ribbons than to let the tendons slough in their sheath, and so infect the whole hand. Some of the cases of whitlow will come to amputation sooner or later. The head of the metacarpal bone should, however, be left. No harm comes of leaving the cut ends of the flexor tendons to look after themselves. As to pus in the palm of the hand, we need not be afraid of hemorrhage when we incise the palm. So, also, with cellulitis; the author has never seen any difficulty or danger from primary hemorrhage in any incision made for the relief of cellulitis, and can recall only one case of secondary hemorrhage. In hospital practice nine cases out of ten of cellulitis require incision—when the inflammation is marked, with severe constitutional disturbance it is a waste of time to wait. In bad cases incisions should be about three inches long and three inches apart, and ought to go their whole length down to the deep fascia. Gauze should be lightly laid in the wounds, the limb be wrapped in gauze for a few hours only, and then fomented with hot boracic lint. It then needs rest, and not perpetual bathing and plugging and moving about. The author firmly believes in the administration of quinine in five-grain doses four times a day, and also in the use of antistreptococcic serum, provided that the infection has been proved to be the work of streptococcus and not staphylococcus.—*Clinical Journal.*

**General Massage with the Inunction of Cod-liver Oil.**—E. J. Kempf reports a case of complete recovery from acute tuberculosis by means of general massage with the inunction of cod-liver oil. The second case was that of a girl suffering from spontaneous dislocation of both knees, who was pale, emaciated, weak and loose-jointed. She had a slight hacking cough and there was an exaggerated respiratory murmur over both lungs. There was the history of pulmonary tuberculosis in the family. After six months of systematic treatment by massage

with cod-liver and olive oil, the patient made a perfect recovery. In a third case of a girl suffering from hystero-epileptic attacks following several bites from a dog, recovery ensued after massage with cod-liver oil.—*Medical Standard.*

**Kryoscopy of the Urine and Ascitic Fluid in Diseases of the Liver.**—Ferraninni seeks to extend the applicability of this method of investigation by employing it in diseases of the liver unaccompanied by noteworthy kidney changes. The intimate relationship existing between hepatic and renal activity would lead one to expect radical changes in the molecular concentration of the urine, independently of any actual lesion of the kidney. The results of his observations confirm this theoretical conclusion, and show that in atrophic, venous cirrhosis $\Delta$ remains within the normal range, but with a tendency to the upper limits; insufficiency of the function of the glomeruli and renal epithelium obtains. In hepatic and splenic enlargement accompanying malaria $\Delta$ reaches and exceeds the upper limits, slight insufficiency of the glomeruli is found. In a case of probable biliary hypertrophic cirrhosis $\Delta$ was always large and hyperactivity of the renal epithelia could be determined. One case of syphilis of the liver gave similar results, while in another with cyst of the pancreas and obstructive jaundice $\Delta$ was very low and the function of both glomeruli and epithelium was markedly modified. A case of simple congestive jaundice and one of carcinoma, both showed a normal value for $\Delta$ and slight glomerular and epithelial insufficiency. In a case of sarcoma $\Delta$ was within the normal limits with slight insufficiency of the glomeruli and more marked insufficiency of the epithelium. The kryoscopic index of ascitic fluid in atrophic cirrhosis was found to be between $-0.55^{\circ}$ and $-0.75^{\circ}$.—*Centralblatt für innere Medicin.*

**Iodoform Filling for Bones.**—Mosetig-Moorhof describes a method he finds useful in securing prompt closure of large defects following extensive operations for chronic bone diseases. The underlying principle consists in filling the cavities made in the bone with a mass which temporarily replaces the loss of substance and is then gradually absorbed as the new bone is formed. The technique is somewhat troublesome, but when carefully carried out is said to produce very satisfactory results in a class of cases that, under the ordinary treatment, are exceedingly tedious. The prime requisite is that a perfectly aseptic cavity is made at the operation, and this is to be accomplished only through the most scrupulous removal with chisel and gauge of every particle of diseased bone, as all attempts at chemical disinfection and even with boiling oil are inadequate. The operation should therefore be conducted under hæmostasis with the elastic tourniquet with the greatest thoroughness, and then rendered absolutely dry by sponging and the application of filtered dry cold, or, preferably, heated air. This is an essential step, and requires the same care as is needed in filling the cavity of a tooth. When the entire bony surface is clean, white, and shining the filling is slowly poured in, in such a manner as to exclude all air bubbles. The composition of the mass is as follows: Iodoform, 60 parts; spermaceti, and oil of sesame, each 40 parts. The constituents are placed in a sterile flask and slowly heated in a water bath to 80° C. This temperature is maintained for fifteen minutes, and then the mass is allowed to solidify under constant shaking in order to keep the iodoform emulsified. When cold this forms a solid mass which, before use, is liquified by heating to 60° C. The bony cavity is filled to the brim with this, and after a delay of several minutes, to permit congelation, the soft parts are sutured, leaving one or two small openings for drainage. A sterile dressing is applied, without great pressure, and only then is the tourniquet loosened. The filled cavity does not bleed nor discharge, and *x*-ray pictures taken at intervals bear witness to the gradual absorption and replacement of the iodoform mass. This, of course, is very slow, but is complete, and in one hundred and twenty cases treated in this way no local reaction or disturbance of healing was observed.—*Centralblatt für Chirurgie.*

**Researches on the Etiology of Sleeping Sickness.**—Aldo Castellani says that, as a result of his investigations, he can state that: (1) In 70 per cent. of cases of sleeping sickness, he has found in the cerebrospinal fluid taken by lumbar puncture during life, a trypanosome which may possibly represent a new species. This trypanosome may be found also in the blood of the patients. In both blood and cerebrospinal fluid he has found special bodies which he is inclined to consider developmental stages of the trypanosome. (2) At the post-mortem examination of 8 per cent. of the cases, he has cultivated from the blood of the heart, and the liquid of the lateral ventricles, a variety of streptococcus which frequently shows cultural characters different from the typical streptococcus pyogenes. The question arises, what part have the two organisms in the etiology of the disease. From the whole of his researches, the author is inclined to think that sleeping sickness is due to the trypanosome described. At the same time, in the last stages there is frequently a concomitant streptococcic infection which must play a certain part in the course of the disease.—*The Journal of Tropical Medicine.*

**Exogenous Perforative Ulceration of the Intestines.**—J. G. Adami reports two cases in which the intestines were perforated by ulceration from without inward. The first was a case of appendicitis, with localized abscess formation, the second a primary tuberculosis of the peritoneum of chronic development with a terminal streptococcic infection. In both there was the existence of ulcers associated with the perforated intestine and showing an incomplete destruction of mucosa, so that a portion of this had been left bridging over the loss of substance beneath. The condition of the mucosa itself indicated that the inflammatory process had not been on the mucous surface; had it been so, the whole of the mucosa would surely have been destroyed before the ulceration extended through to the serous surface. From a study of hospital records, the author believes that these cases are more frequent than is generally supposed.—*The Montreal Medical Journal.*

**A Case of Colon Infection Simulating Typhoid Fever.**—Joseph Evans and Joseph Sailer report a case which, though incompletely studied, still indicates that it is not impossible that some obscure cases of continued fever in which the blood does not react either to the typhoid or paracolon bacilli, may be actually due to general colon infection. The numerous tests that were made in this case tend to prove that although typhoid sera will sometimes agglutinate the bacillus coli communis, yet not in as high dilutions as the bacillus typhosus; also, that this case was not one of simple continuous fever, but was really a colon infection; again, that it was not a case of typhoid infection with delayed Widal reaction. The case appears to be one of pure colon infection with the colon bacilius similar to that used in making the tests—the bacillus that was isolated at the Pasteur Institute in Paris. Unfortunately a blood culture could not be made, and it cannot be known positively whether a similar microorganism was present in the blood of the patient or not. Certain sources of error must therefore be considered theoretically possible. The present culture, however, was recognized as colon at the Pasteur Institute. It ferments all sugars; it gives a strong indol reaction, and therefore is identical with the colon bacillus according to all the usual differential tests. It is, however, actively motile. The blood of the patient did not give any reaction with proved cultures of the typhoid bacillus, nor with four varieties of the paracolon bacillus. Hence, the infection was presumably not typical of any of these forms. The most reasonble hypothesis with regard to this case is that it was one of infection with the colon bacillus, and resembled in its clinical course an infection with the typhoid bacillus. Examination of the literature has not so far discovered another case of this nature.—*University of Pennsylvania Medical Bulletin.*

## GLYCOSURIA AND DIABETES.

A DEBATE on diabetic and non-diabetic glycosuria was held at a recent meeting of the Chelsea Clinical Society. The discussion was opened by Dr. W. Hale White, who began his paper by defining diabetes proper, termed by Dr. Pavy composite diabetes, as a disease in which dextrose is present in the blood and urine; and in which, if the disease be untreated, ultimately lavo-rotary B. hydro-oxybutyric acid appears in the blood and urine, and the output of carbohydrates in the urine is greater than can be accounted for by those in the food. The gist of the author's further remarks was as follows: Although in the early stages excess of sugar in the urine and blood is very largely due to the failure of the body to utilize the sugar, in many cases the power to utilize sugar is not entirely lost, and sometimes in a severe case of diabetes there may be sugar in the blood and urine even if carbohydrates are entirely absent from the food. According to Hesse, such sugar must come either from proteids or fat, and the prevailing opinion is that it comes from the proteids, for, in the first place, diabetics do very well on fat, and in the next place, only a little sugar could be produced even from a large amount of fat.

Dr. White thinks that the next point of interest is not nearly sufficiently grasped—namely, that many diabetics can utilize levulose much better than dextrose. This ability to utilize levulose suggests that experiments might be made to see whether diabetics can utilize other sugars. The extraordinary fact pointed out by Dr. Pavy many years ago that a diabetic patient who is on a strictly carbohydrate free diet, may, if a little carbohydrate be given, excrete far more sugar than that given, is worthy of close attention. Again an explanation is required of the strange disappearance of sugar when coma comes on. In a debate on diabetes much attention must be given to coma. At the present time the prevailing view is that the coma is in some way dependent on the lavo-rotary hydro-oxybutyric acid which is found in the blood of a patient in diabetic coma. From various experiments and investigations made, and especially by Dr. Spriggs, it appears that in diabetes there is a poison which has two effects—namely, the production of coma and the lessening of carbon-dioxide in the tissues, and the view that this poison is in some way closely allied to oxybutyric acid coma is strongly supported by the fact that sometimes coma is benefited by giving alkalies.

With regard to the morbid anatomy of composite diabetes, Dr. White says the points on which information is needed are these: (1) Is alteration in the islands of Langerhans the essential feature of the pancreatic disease which causes diabetes? (2) Can we tell during life which cases have and which have not pancreatic disease? and (3) What is the relationship of the internal pancreatic secretion to diabetes?

The last point which the author puts forward is whether we are not under the word "diabetes" really describing more than one disease, for example, are some cases due to diseases of the pancreas and some not? Are those that have so-called fatty blood different from those that have not? Are those in which glycogen is present in the liver different from those in which it is absent?

In the discussion which followed the reading of Dr. White's paper Dr. Pavy reserved his remarks to a consideration of the distinctive features of diabetic glycosuria and non-diabetic and Dr. Saundby defined these conditions thus: Diabetic glycosuria is a glycosuria in which assimilation failed and non-diabetic glycosuria was that in which assimilation was not at fault.

Dr. J. Rose Bradford said glycosuria might not only be of mixed origin when it was of non-diabetic origin, but even when due to diabetes it was probable that many distinct and separate forms would be recognized in the future. It was worthy of notice that although the presence of glycosuria was so intimately associated with diabetes, yet that disease might exist and be fatal where no sugar was present. From a consideration of the disease itself, and especially from the results of physiological inquiry, it would seem that some five varieties of diabetic glycosuria might perhaps be described, although in the present state of their knowledge it was not possible to separate all of them clinically. Firstly, there was evidence in favor of the existence of glycosuria as a result of disturbed function of the absorptive and other mechanisms of the alimentary canal, so that a definite alimentary variety of glycosuria, characterized mainly by the intimate relationship of the glycosuria with the carbohydrates ingested, might be recognized. Secondly, most authorities would admit that glycosuria might have a hepatic origin, dependent perhaps on the liver not arresting the glycogen brought to it, and possibly in other instances dependent on the liver, forming too much sugar. Thirdly, a pancreatic diabetes might be admitted to exist, both from the experimental standpoint and from that of human morbid anatomy. Fourthly, it was probable that a renal glycosuria existed, especially in the light of experimental results obtained with phloridzin, as it would seem that this glucoside caused glycosuria by an action on the renal cells. That opened up the whole question of the relationship of morbid processes in the kidney to diabetes and might place in a new light the well-known fact that in certain cases of diabetes the kidney was greatly hypertrophied. This, in the author's opinion, could not be associated simply with the increase of urine excreted, as renal hypertrophy was by no means an invariable accompaniment of diabetes. Further, the fact that glycosuria might disappear in a case of diabetes when

an acute renal complication, such as Bright's disease, supervened might also receive a new explanation in the light of these phloridzin results. Fifthly, it had been suggested, and should at any rate be admitted as possible, that a diabetic glycosuria might arise as a result of a primary disintegration of the tissues. In this enumeration—concluded Dr. Bradford—of the possible varieties of diabetes the nervous system had been omitted, as although the fact that the nervous system played a part in the production of the disease, must be admitted. On clinical grounds, there was only evidence from the experimental standpoint that lesions of the nervous system produced glycosuria rather than diabetes.

---

## THE NEWER CONCEPTIONS OF "MATTER."

It is now some years since Crookes reported on his investigations upon "radiant matter," and since then we have had added a number of phenomena, more or less similar, under the names of Becquerel rays (which were observed to be radiated by uranium), the Röntgen rays, and, last of all, those given off from the newly-discovered metal, radium, and its congeners (polonium, thorium, actinium). The story of the development of this branch of physics-chemistry is in itself one of surpassing interest, but it bids fair to be eclipsed in importance and interest by the new light which has been thrown upon the almost "ultimate" problem of the constitution of matter. By "matter" we mean *substance* in the *atomic* condition. "Substance" is a broader term, and will serve to denote, in addition to "matter," at least one other thing, the ether. As Professor Lodge puts it: "Matter is that which is susceptible of motion. Ether is that which is susceptible of stress. All energy appertains either to matter or to ether, and is continually passing from one to the other." We cannot, of course, go into these fascinating questions *in extenso*, but we think we will do our readers a service if we lay before them some of the results which seem fairly assured, from the work along these lines during the past few years. We are moved to do so by a cablegram in *The Sun* of the 21st instant. From this it would seem that Professors Crookes, Lodge, and Curie (the discoverer of radium) feel it now safe to commit themselves to a definite pronouncement to the effect that what we have hitherto called "atoms" are in reality compounds of almost infinitely smaller parts, or "corpuscles." They further consider that these corpuscles, from whatever kind of atom derived, are all alike. The apparent properties of each "atom," then, would be due to the number and arrangement of the component corpuscles. The internal composition or structure of the atoms, may be regarded as analogous to that of a solar system, the numerous corpuscles revolving within orbits in accordance with laws which prescribe more or less closely their intra-atomic paths. Under some circumstances it is now known that at least some of these corpuscles can leave the atom, and without destroying it. It further seems probable that under certain other circumstances the process may involve destruction of the atom—perhaps its resolution back into the unorganized ether from which it would seem that the atoms originally came. At least we know this much, that under the conditions of evolution of the "*x*- (or Röntgen) rays," the atoms are broken up into two parts—a very large part which is immobile and is positively electrified, and a very minute part which is negatively electrified and which by its rapid flight produces the phenomena of the "*x*-rays." These latter corpuscles, as Lodge has explained, cannot be atoms because, for two reasons, they move too fast and too far. By means which Lodge describes at length, it has been found possible to measure these negatively charged atom-fragments with the result that their mass is about 0.002 that of the atom of hydrogen; while, on the contrary, the magnitude of their electric charge represents that of the whole atom. These negatively charged particles do not differ *inter se* from whatever kind of atom they were derived; and accordingly they can fit themselves on to any kind of positively charged atom-residue with which they come into contact, whether that residue is of the same kind of atom as that from which they emanated or not. Further the evidence seems to indicate that all the other corpuscles which go to make up the positively charged atom-residue are of the same kind as the negatively charged one which we have been considering one, though no individual positively charged corpuscles have as yet been actually observed. Supposing these results to be, as they now seem, well founded, Mencdeleeff's Periodic Law would presumably find its explanation in an ability of the corpuscles to form (approximately) stable combinations in those proportionate multiples which constitute the atomic weights of the several "elementary" substances; the presumption being, as Professor Lodge points out, that other and intermediate proportions probably did not involve stability. Though we are now rather far in the region of hypothesis, still the phenomena exhibited by radium seem to indicate that under certain conditions corpuscles can fly off from the atom somewhat as meteors leave a solar system. At least this hypothesis seems to be the only one which would harmonize the observed facts with the law of the conservation of energy, for radium continuously gives off heat, and light (rays of the class of the "*x*-ray"—that is, rays penetrating substances ordinarily called "opaque"). Whether this energy is produced at the expense of the weight of the radium is, of course, the crucial question, and one which cannot be said to have been settled so far, Becquerel and Thomson affirming that the loss of weight is almost infinitesimal, while Heydweiller asserts that it amounts to 0.02 milligram per day. Whatever the fact may be as regards this question, it is certain that the amount of energy given off is enormous, a radium salt emitting sufficient heat to melt its own weight of ice every hour, and maintaining itself constantly at a temperature of 1.5° C. above that of the surrounding medium. And Professor Curie said that he would not care to stay in a room with a kilogram of radium as it would burn all the skin off, destroy the eyesight, and probably kill. Thanks to the researches of Rutherford, the Curies, Becquerel, and others, we now know that radium emits three distinct classes of rays, designated in the order of their penetrating power, *a*, *b*, and *c*. The first class forms the largest and most important section of the rays, and there are reasons

for believing that perhaps these may represent corpuscles *positively* electrified, as the "*x*-ray," represent corpuscles negatively electrified. That the phenomena of all these radiations are, at the least, similar to electrical manifestations, is shown by the deflection of these rays from the straight line by a magnet. But into the question of the nature of electricity and its relation to "matter," we cannot go. Suffice it to say that it seems at present to be as close as was formerly that of husband and wife, in the days when they were "one."

## CAUSES OF CANCER

In the May issue of the *London Polyclinic*, of which Mr. Jonathan Hutchinson is editor, is an article on the causes of cancer. The question is discussed from the point of view of a study of the disease as it is met with among the native population of India, which would seem—declares the writer—to give emphatic support to old opinions, foremost among these being the doctrines of origin in the individual from local irritation, and of perpetuation in the community by the transmission of inherited tendency.

In India there are, in comparison with Europe, but few new growths of malignant origin, and this is especially so in the case of those of the epithelial or carcinomatous variety as contrasted with the sarcomatous forms. The trend of the argument of the article in the *Polyclinic*, is as follows: Phymosis has long been recognized as a condition which powerfully predisposes to epithelioma of the penis, and it has been often urged by the advocates of circumcision that this rite tends to prevent cancer. Jews are pointed to as striking examples of the accuracy of the statement, it being extremely rare for an individual of this race to suffer from epithelioma of the penis. In India, too, this teaching receives confirmation on a large scale. There is an immense Musulman population, all of whom are circumcised, while the penis is rarely affected with the above form of the disease. The Hindoos, however, who have long foreskins, and are careless as to personal cleanliness, suffer frequently. Among the inhabitants of India the next most common part of the body to be attacked by cancer is that of the inside of the mouth. The tongue, the mucous membrane of the cheeks and of the floor of the mouth are affected in a fair number of cases, but cancer of the lips is seldom met with. These facts are easily explained. Smoking is not a frequent custom, and the short clay pipe is never used by the native of India. Although smoking is seldom indulged in, chewing is a universal habit. The substance, too, which is chewed—the betel leaf admixed with lime and other ingredients—causes a constant irritation of the mouth.

In certain parts of India, there is another kind of epithelial cancer to which the inhabitants are prone. The disease in such cases attacks the abdomen, and can be plainly traced to local irritation. Dr. Elmslie who first drew attention to its prevalence, attributed the disease and its uncommon location to the local habit of carrying what is called a kangri—a portable earthen brazier—under the clothes. This article is protected by wickerwork, but is often placed close to the skin under a loose woolen gown. In the erect posture it hangs on the abdomen, but when sitting it is placed between the thighs. Other medical men practising in those parts where the kangri is worn have fully confirmed Dr. Elsmlie's observations.

The writer then sums up in these words: "When it is realized that the three groups of cancer cases which have been mentioned—of the penis in the uncircumcised, of the mouth in the betel chewers, and of the skin of the abdomen in the kangri wearers—constitute the great bulk of the cancers met with in India, the importance of local irritation as a cause of the cancerous process stands out very definitely. We do not wish to be premature, nor in any sense to throw cold water on the zealous efforts of those who are seeking for the cause of cancer in the laboratory, but it is difficult to avoid a strong *primâ facie* impression that such facts do not favor the theory of parasitic origin. On the other hand they appear to point with steady finger to the means of prevention, and in the early stages to those of cure. How can a process which may result from the irritation of retained smegma, or the heat of a pocket brazier be supposed to be due to parasitic contagion? Let the microscope show what it may, how can cancer ever be remediable by any other means than by avoidance of its exciting causes and prompt removal of the result at the earliest possible opportunity"

## SOIL NITRIFICATION AS A PREVENTIVE OF MALARIA.

In the *Lancet* for June 6, Dr. Arthur Waddel writes on the effectiveness of ammonia as a means of destroying the larva of mosquitos. In the course of experiments that he carried out last summer, he found that attenuated solutions of ammonia had a deadly effect upon mosquito larvæ. From this fact he draws the conclusion that here we have a force of enormous potentiality in the crusade against malaria, and one, moreover, which is capable of practical application. This force consists in the effective nitrification of the surface waters and vegetation through the medium of the soil, the former checking the existence of the larva, and the latter being inimical to the adult mosquitos. The writer explains that nitrification of the soil may be brought about in two ways: First, by the direct application of nitrogenous manures, and, secondly, by fostering the growth of certain plants belonging to the leguminosæ, which are known by their peculiar root action to add to the nitrogen in the soil. The growth of these plants may be encouraged and stimulated by the use of phosphatic manures and also by inoculating the ground and the seed to be sown on it with cultures of those earth bacteria, which are sold commercially under the name of "nitrogen." The bacterial organisms themselves are, however, the real nitrifiers, the leguminosæ being dependent upon their presence at the roots for healthy growth. These organisms abound in all good cultivated soils in which there is a sufficiency of phosphates, potash, and lime, the last especially being of vital necessity to them, and they are most active at a temperature of about 99°F., cold and absence of moisture inhibiting them. Good cultivation assists them. Dr. Waddell points to Great Britain as a most striking example of the beneficial effects of nitrification of the soil in extirpating malaria. Although, of course, he allows that improved drainage has had much to do with

bringing about this state of affairs, yet he contends that other factors have helped toward this consummation, and amongst these the nitrogenization of the soil by the widened use of phosphatic manures, the extended growth of clovers and the enormously increased use of nitrogenous manures have played an important part. Dr. Waddell, therefore, suggests that no time should be lost in making practical tests to establish the most effective way of employing soil nitrification against the distribution of malaria. He thinks that the irrigation areas of India and parts of the Roman Campagna would be suitable districts in which to undertake experiments of such a nature. An area of the cultivable portion might be taken in hand, one part of which might be nitrogenized directly, and another part dressed with phosphatic manures and heavily planted with leguminosæ. Ammonia is well known to have a strong inhibitory effect upon low forms of animal life, the nematode worms, for instance, which live parasitically in the alimentary tracts of horses, cattle and sheep, and which in the two last-named animals set up a wasting disease characterized by scouring diarrhœa. These ammonia destroys with great celerity. That ammonia is equally effective in destroying mosquito larvæ, there would seem to be no reason to doubt. Consequently the suggestion of Dr. Waddell that nitrification of the soil will prevent the existence of mosquitos and therefore of malaria is one based upon sound reasoning.

---

### Education and Birth Rate.

It has been asserted often, and especially during the past few months, that a decrease in birth rate goes hand in hand with an increase of education. At first sight this view of the question does not seem to be an unreasonable one, judging from the experience of the past. Rome and Greece were, perhaps, never more highly educated and cultured than when in their decadence and when the birth rate of their native-born inhabitants was at its lowest. In modern times France is the most cultured, if not the most highly educated and learned of nations, and in that country the birth rate is the lowest of any land.

A distinction must doubtless, however, be drawn between culture and education, for that education does not necessarily imply a decreased birth rate is shown by the case of Germany, in which country mental training has been carried to the highest possible pitch, and where, too, the birth rate is large and increasing. Dr. George J. Engelmann has—so far as the United States is concerned—been investigating into the causes of the undoubted great falling off in the birth rate of native-born Americans, and writes on the subject in the *Popular Science Monthly*, for June,

He is not of the opinion that education is a potent cause of the small families of Americans of native stock, but rather takes the opposite view. Dr. Engelmann sums up the matter, from his point of view, as follows: "The data now available indicate that the highly educated male element does more toward reproducing itself than any other large group of our native population. The marriage rate is the same, and the number of surviving children to the family is greater than it is for the native population at large, so that we can no longer accuse the college graduate, or, if I may say, 'the highly educated male portion of our population,' of having an exceptionally small family, and of doing less than other groups toward reproducing the population; nor must we lay the blame for the low fecundity of the native American family on higher education. Shortening the term of college study will effect no change. Wealth, luxury, and social ambition are the cause of the diminishing size of the family and of race decline. The factors are the same as those which have been active in earlier civilizations; increasing wealth and the introduction of foreign manners are pointed out as causing, in ancient Rome, the lessening fertility among the better classes which preceded political disruption. Cause and effect were the same and even the methods employed to thwart the tendencies of nature were the same." In a few words Dr. Engelmann brings forward the charge that among Americans of all classes criminal measures are resorted to in order to prevent conception or to produce abortion, and that to these methods are due the diminishing birth rate of the native-born race. The writer, indeed, goes so far as to declare that the birth rate of the New England States is less even than that of France, but he absolves the educated class from being to blame for this condition of affairs.

---

### Study of Snake Venom.

Drs. Simon Flexner and Hideyo Noguchi, during the past two years, have been studying, at the University of Pennsylvania, the venom of poisonous snakes. The investigations thus far have brought out facts of a valuable nature, and it is believed that antidotes for all kinds of venom in course of time may be discovered. The venom is extracted after the snakes have been chloroformed, and, in experiments with live animals, is injected hypodermically. The reason for this procedure is that on occasions the snake does not strike so as to inject venom sufficient to do any harm, while, at the same time, to an onlooker, the bite may appear to have been a terrible one, and may cause an antidote administered to be wrongfully regarded as effective. By injecting the venom hypodermically no mistake can be made, and a correct judgment can be formed as to the value of the antidote used.

The experiments generally have demonstrated the uselessness of the popular antidotes. Alcohol has been shown to be of great service—as a stimulant, however, and not as an antidote. That individuals who have been bitten by particularly venomous snakes are able to imbibe very large quantities of alcohol with beneficial results and without exhibiting signs of drunkenness,has been known almost from time immemorial. Experiments conducted upon snake-bitten animals, of dosing them with alcohol, have been attended with like results. The effect has been to keep up the action of the heart, whilst the excessive prostration produced by the presence of the venom in the system is continued. If this object can be accomplished sufficiently long for the effects of the poison to pass off the victim will recover.

The intermittent ligature was found to be the most valuable mode of treatment of snake-poisoning. This method, in conjunction with alcohol given each time the ligature is loosened, had an excellent effect in counteracting the prostrating influence of the venom entering at intervals in small quantities. Other experiments of an interesting and valuable character have been carried out by Drs. Flexner and Noguchi. The Carnegie Institute has recently granted $1,000 to aid in the investigation of snake poison at the University of Pennsylvania.

### Health of the British Army.

A blue-book has recently been issued containing the statistical report of the health of the British troops at home and abroad for 1901. It is stated that the average strength of European troops serving at home and abroad, exclusive of South Africa in that year, was 196,796. The total number of admissions to hospital was 172,908, and the total number of deaths 1,762. The admissions represent a ratio of 878.6 per 1,000 of strength; the deaths one of 7.70 per 1,000, or a strength of 228,816, which includes detached men not shown in the returns received. Amongst the troops serving in the United Kingdom the admission and constantly sick rates were higher and the mortality rate lower than in 1900. At Gibraltar the admission, death, and constantly sick rates were lower than in 1900. In the Malta command, which included Crete, the admission, mortality, and constantly sick rates were slightly higher than in the previous year. Malarial fevers furnished a higher admission rate than in the year preceding, the large increase in the number of cases being due to the prevalence of ague in Crete. The medical officers attribute the cause of the outbreak to the bite of infected mosquitos. In Canada the health of the troops was good, there being a decrease in the admission rate, but an increase in the mortality and constantly sick ratios as compared with 1900. Yellow fever caused five admissions and four deaths at St. Lucia, the disease having been probably imported into the colony by shipping from South America. In Western Africa malarial fevers, not so prevalent as in previous years, furnished, as usual, the majority of the admissions. As regards South Africa, no annual returns of sick have been submitted, and statistics for comparative purposes cannot, for the present, be prepared. In India there was a decrease in the admission, mortality, and constantly sick rates, but an increase in the invaliding ratio. As regards typhoid fever, it is noted that not since 1887 has there been a lower admission rate while the death rate is less than in any year since 1884. In Egypt the admission, death, and constantly sick ratios were higher than in 1900, open-air treatment for tuberculous diseases was introduced at the Station Hospital, Cairo.

---

**"The Journal of Infectious Diseases,"** a new magazine to be established at the University of Chicago, has been endowed by Mr. and Mrs. Arnold F. McCormick, the parents of John D. Rockefeller's favorite grandson, whose death from scarlet fever three years ago inspired the establishment of the Rockefeller Institute for Medical Research. The magazine is to be distributed free of charge to libraries and to sanitary experts of various cities. Dr. Ludvig Hektoen, head of the department of pathology and bacteriology at the university, and Dr. Edwin O. Jordan, associate professor of bacteriology, are to be the editors. The first number will appear from the University of Chicago press on January 1.

**A Surgeon Operated upon by His Wife.**—A correspondent of the New York *Times* relates a remarkable story of wifely devotion. Dr. W. H. Logan, he says, formerly of Bethany, Ill., but for many years a medical missionary in China, was recently attacked by appendicitis. Realizing that recovery lay in an operation involving the removal of the appendix, he called his wife and imparted a diagnosis of his own case. Mrs. Logan, unassisted, but guided by the instructious given before her husband's relapse into unconsciousness under anæsthetics, performed the operation. Under skilful ministration of the wife-nurse, such favorable progress was made toward recovery in short time that Mrs. Logan determined to remove him where he could have the benefit of skilled surgeons.

## News of the Week.

**Registration of Births and Deaths in Illinois.**—Under the provisions of a law enacted by the last General Assembly of Illinois, which went into force on July 1, physicians and midwives in the State are required to report births to the county clerks, except in the cities of Chicago and Peoria, in which reports will be made to the Commissioner of Health. A fee of twenty-five cents will be paid for each birth reported, either to the county or city official. The State burial permit law of 1901 has been repealed, to take effect the first of July. Under the new law, physicians, midwives, and coroners are required to report deaths direct to the State Board of Health, except in cities which have burial permit ordinances. In these the local authorities are required to send monthly, to the State Board of Health, all certificates of death presented to them. A fee of twenty-five cents will be paid physicians and midwives for each report of death made to the State Board of Health. It is made the duty of the State Board of Health to forward all certificates of deaths to the county clerks for final record. It is believed that this law will be more satisfactory than that now in force. Under its provisions the State Board of Health will be promptly advised of the number and causes of deaths in each locality, and will be in a position to investigate immediately any undue prevalence of disease, and take the necessary action to protect the public health.

**The work of the Milk Commission of the Medical Society of the County of New York.**—The warm season is at hand when food is preserved with difficulty, and when deaths from summer diarrhœa in infancy become numerous. Since many of these deaths are due to unwholesome milk which is produced in dirty dairies, is never efficiently cooled and is very old when delivered to the consumer, such milk, on account of chemical changes and its myriads of bacteria, being unfit for infant feeding, the Milk Commission of the Medical Society of the County of New York has called attention to the inspection and certification of milk under its supervision, the general use of which should tend to diminish materially this great factor in our death rate. The inspected milk is produced at dairies which are inspected at regular intervals by the inspector of the commission. The stables are clean and are provided with facilities for cleaning the hands of the milkmen. The water supply, the milkers, the utensils, the cattle and the transportation are all subject to requirements necessary for producing a clean and safe milk. This inspected milk may be bought in bulk for institutions or in bottles for families at or about the same price as ordinary milk. Each bottle contains a cap marked "Inspected by the Milk Commission of the Medical Society of the County of New York." Certified milk is a still higher grade of milk produced under very stringent rules. Thus among other things it is required that the dairies producing this milk should sterilize all bottles and other utensils and seal and date every bottle of certified milk. Certified milk is sold at a somewhat higher price than inspected milk. The members of the Milk Commission are Drs. E. K. Dunham, chairman; Rowland G. Freeman, secretary; W. L. Carr, H. D. Chapin, A. Jacobi, A. Lambert, W. P. Northrup, W. H. Park, G. M. Swift, and J. E. Winters.

**A Kishineff Physician Punished.**—A despatch from a press correspondent at St. Petersburg states that Dr. Dorosbevsky, who was equally indefatigable in his attentions to the victims of the Kishineff massacre and in his fearless pub-

lication of the truth concerning the massacre, has been forced to resign his place in the Bessarabian Provincial Hospital at Kishineff. A Russian paper declares the reason for this to be that he published facts, figures, and names which certain persons wanted kept secret.

**Sir Frederick Treves to Retire.**—A despatch to *The Sun* says it is reported that Sir Frederick Treves of London, who performed the operation upon the King for intestinal trouble, will retire from practice at the end of July. He will retain the honorary post of surgeon to the King and adviser to the Army Medical Board. As he is only fifty years old and is full of energy, it is suggested that he closes his surgical career for the purpose of entering Parliament.

**A Victory for the Advocates of Sanitary Tenements.**—The Tenement-house Commission has won an important legal victory in its fight for healthy tenement-houses. Suit was brought against the owner of a tenement house who had violated Section 100 of the amended tenement-house law by maintaining the old-fashioned "school sinks" on the premises. The case was contested chiefly on the ground that the law requiring this removal was unconstitutional because unreasonable, in view of the expense involved, as well as because the school sinks, if properly taken care of, were sanitary. It was shown by the prosecution, however, that these school sinks are practically yard privies with a sewer connection, and they have proved to be dangerous sources of disease and are under the ban of most intelligent sanitary opinion. The expense of substituting waterclosets, either in the house or in the yard, was also shown to have been very grossly exaggerated, and it was asserted that many owners of tenement-houses had made the change voluntarily, finding that the value of their property as an investment was greatly increased thereby.

**The New Jersey State Medical Society** held its annual meeting at Asbury Park last week. Dr. Henry Mitchell of Asbury Park was elected President. The next annual meeting will be held in Atlantic City.

**A Versatile Physician.**—A physician in a Texas town probably holds the palm among his confrères for the number of irons he has in the fire and presumably strikes when they are hot. He is the proprietor of a hotel in his town, and also, according to the statement on his letter-heads, of a drug store, a livery stable, a blacksmith shop, a harness store, a buggy store, and a newspaper.

**The Beginning of a Great Sanitary Undertaking in New Orleans.**—On June 25 Mayor Capdevielle of New Orleans turned the first spadeful of earth in the work of constructing the vast system of sewerage, water and drainage, which is to cost $18,000,000. It is hoped that the undertaking will be completed within the next five years.

**A Nurses' Home on Blackwell's Island.**—Plans were filed a few days ago with the Manhattan Bureau of Buildings for a four-story brick nurses' home, to be built on Blackwell's Island at a point opposite Fifty-first street. The building, which is being erected by the city, will occupy a plot 107x 35.2 feet, and will cost $65,000.

**Smallpox at Bordentown.**—A number of cases of smallpox have been discovered at Bordentown, five miles from Trenton, N. J. Seventeen persons are down with the disease, and the principal hotel in the town, the public schools, the churches, and the telephone exchange have been closed.

**Enforcement of the Pure Food Law.**—The Treasury Department has sent a circular to the customs officials instructing them how to act, under the pure food law which went into effect July 1, in the matter of holding up imports which are suspected of being adulterated or injurious to human health. The customs authorities are required to draw samples from such goods and forward them to the Bureau of Chemistry in the Department of Agriculture for chemical analysis. The importer whose goods are challenged is to be given a notice of the fact, and is to have the right within two days to be heard in defence of the quality of the articles imported. When the chemist has made his report, the goods, if found to be adulterated, can be exported or destroyed according to the decision of the consignee.

**The Annual Tetanus Outbreak** may be looked for in the next few days or weeks as a result of our Chinese fashion of celebrating Independence Day. As prevention is better, and more easy of attainment, than cure, all wounds made by explosives, especially if in the hands, should be freely opened and washed out with large quantities of sterilized salt-solution, and as a further precaution an injection of tetanus antitoxin should be given. This is urgently recommended by the New York State Board of Health in a recently issued bulletin. According to the rules published by the Jenner Institute of Preventive Medicine in London, 10 c.c. of tetanus antitoxin should be injected every fortnight for six weeks. The dose for curative treatment is much larger, according to this authority, as much as 10 to 20 c.c. being injected every six to twelve hours, according to the urgency of the symptoms and the duration of the incubation period. As a rule, the shorter the incubation period is, the more severe is the disease and the larger and more frequently repeated should be the dose.

**Knock-out Drops Administered to a Health Officer.**—An assistant surgeon in the Marine Hospital Service, acting as quarantine officer at San Juan, P. R., and his wife were drugged with chloral put in lemonade and robbed at the Hotel Inglaterra in that city one night last week. While they were under the influence of the drug all their money and jewelry were taken from a bureau in the room. A porter who took the lemonade to the victims has been arrested on suspicion.

**Indiana Grave Robbers Freed.**—Six negroes and two white men, who have been in jail in Indianapolis since November last on charges of grave robbing, were released last Saturday through the failure of the State to secure evidence upon which to convict them. The man on whose evidence they were indicted has been sent to prison and now refuses to testify further in the case. When releasing the prisoners the State prosecutor said he would not try the physicians who are under indictment for receiving stolen bodies, as it would be impossible to convict them without evidence, though more than thirty bodies, he said, were proved to have been stolen and delivered to the medical colleges.

**Health Board Sales of Antitoxin.**—In a letter to the Mayor, Health Commissioner Lederle of this city has recommended stopping the sale of diphtheria antitoxin to persons outside the city. He says that the sale of antitoxin by the city is no longer justifiable, as the antitoxin made by private parties is now of as high grade as that produced by the department. He points out that of the $75,000 worth of antitoxin made annually by the city the greater part has been distributed gratuitously, but says that stopping the sale to persons outside the city will decrease the receipts of the department by about $12,000. To meet this loss he suggests an increase in the appropriation.

**A New St. Elizabeth's Hospital.**—Plans have been filed with the Building Bureau for a new five-story and basement hospital to be built on the north side of Fifty-first street just west of Ninth avenue. The building is to be erected for a new St. Elizabeth's Hospital under the charge of the Sisters of the Third Order of St. Francis. The new hospital is to be known as the "Sisters' Hospital." It will have a fifty-five foot front, with a facade of brick, limestone, and terra cotta, and will cost $70,000.

**Dr. Weir Mitchell on Athletics.**—In a letter written by request to the senior class of the University of Pennsylvania, Dr. S. Weir Mitchell says: "You have lost out of college life that which it were better to have kept. We played hard in my college days, but we talked of our sports less than you do. You, I fear, care too little for your intellectual athletes. Athletic sports are meant, as I see them, to insure that the body shall be made and kept sound."

**The Health of Cuba.**—Señor Quesada, the Cuban Minister at Washington, in reply to a query regarding recently published reports of an outbreak of fever at Puerto Principe and other interior points, has received from the Cuban Secretary of State an emphatic denial of the reports which, he says, are without foundation. The sanitary conditions, he added, left nothing to be desired.

**Dismissal of a Health Officer.**—At a recent meeting of the Rochester, N. Y., Common Council, the recommendation of the public safety committee, which had been investigating the recent smallpox epidemic in that city, that the Health Officer be dismissed was adopted by the council. It was declared that the discharged official had been inefficient during the epidemic.

**A Woman Ambulance Surgeon.**—Dr. Emily Dunning, a member for the past six months of the house staff at Gouverneur Hospital, began on July 1 her term of service on ambulance calls. The work will no doubt be trying, but the plucky young lady has performed her duties as junior surgeon so satisfactorily that there is little question as to the successful outcome of her ambulance service.

**Obituary Notes.**—Dr. JOHN W. F. MOORE of Butler, Pa., died June 14 from injuries received by walking into an unguarded areaway. Dr. Moore was born in Armstrong County, Pennsylvania, thirty-five years ago. He received his education at Indiana State Normal School, and was graduated from Jefferson Medical College in 1894, locating soon after at Butler. He was ex-president of the Butler County Medical Society, member of the Pennsylvania Medical Society and the American Medical Association. He was surgeon to the Butler Hospital, and surgeon for the Bessemer and Lake Erie Railroads. Dr. Moore was a man of unusual talents, whose uniform courtesy, gentleness, and sympathy endeared him to everyone with whom he came in contact.

Dr. NELSON H. HENDERSON of Chicago died of septicæmia on June 24. On May 13 he operated upon a woman suffering from pyæmia, opening an abscess in the arm. He wore rubber gloves, but they were defective and some of the pus entered and came in contact with an abraded surface where there had been a hangnail. Dr. Henderson was a graduate of the College of Physicians and Surgeons, Chicago, and was surgeon to the Lakeside Hospital.

Dr. NATHANIEL P. WASHBURN, formerly of Stamford, Conn., died on June 22 at San Antonio, Tex. He had been a sufferer for several years from tuberculosis and had visited a number of places in all parts of the country in the hope of relief by climatic treatment.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

ROYAL HELPERS FOR HOSPITALS AND MEDICAL CHARITIES—THE KING AND QUEEN AT ST. PAUL'S CATHEDRAL AND AT THE LONDON HOSPITAL—THE PRINCE OF WALES AT THE ROYAL MEDICAL BENEVOLENT COLLEGE—THE GREAT BALL AND OTHER FESTIVITIES.

LONDON, June 12, 1903.

THE whole week has been practically devoted to begging for hospitals and medical institutions. Of course many of us were begging in advance, but the week has been full of celebrations and entertainments on behalf of the same objects.

The Royal family—always so anxious to promote medical charities—has been to the fore, sparing no trouble, pleading earnestly for the sick and suffering, and testifying gratefully to the value of the generosity and self-denying work of the profession

The King and Queen, accompanied by Princess Victoria and preceded by other royal personages, attended divine service on Sunday afternoon at St. Paul's cathedral on behalf of the London hospitals. Next Sunday is the day fixed for the collection in other places of worship for the Hospital Sunday Fund, but their majesties were unable to go on that day, and the St. Paul's service was therefore held as stated. The offertory amounted to £4,300.

The announcement of the amount was made on Monday by the Lord Mayor in presiding at a meeting he had called at the Mansion House to promote the same object. The Archbishop of Canterbury, Sir Douglas Powell, Sir Frederic Treves, and Sir W. Church addressed this meeting. Sir F. Treves insisted on the increased need of support in consequence of the improved but costly methods of treatment, and pointed out that the hospitals repaid many times over whatever wealthy persons subscribed by the better medical services that scientific progress placed at their disposal. The Lord Mayor is working hard to make this year's collection a record.

On Monday afternoon the Princess of Wales opened a new nurses' home in connection with the British Lying-in Hospital, which was founded in 1749. The new home has cost about £7,000. The same afternoon the Duchess of Albany opened a new building at Kingston-on-Thames acquired for the extension of the Nursing Home, which was opened by His Royal Highness nine years ago.

On Monday night the King and Queen, accompanied by Princess Victoria, attended a special performance at His Majesty's Theater given in aid of Guy's Hospital. At the close Mr. Tree announced that the sum taken for seats amounted to £2,100 and the expenses would be *nil*. This sum will cover the expense of modernizing Luke ward and endowing a bed in perpetuity to be named after this theater and used exclusively for members of the theatrical profession. Guy's is still asking for £80,000.

On Tuesday night the great ball in aid of the London Hospital, organized by some of the most fashionable people, was held in the Albert Hall, which, I am told, was transformed for the occasion into "a palace of flowers." People who spend much of their time in such entertainments speak of this ball as the biggest and smartest thing of the season. It was not merely a social and artistic success, but it was also a financial success.

Wednesday was a great day for the Royal Medical Benevolent College. The Princess of Wales presided at the festival banquet which had been looked forward to with high hopes. Nearly 500 persons sat down to dinner and much enthusiasm prevailed, especially during the Prince's speeches, which were full of appreciation of the profession. In replying to the toast of the Royal family the Prince said he knew, from the Queen and other members of his family, that the medical profession could ever rely on hearty sympathy and ready support. As to the college, the Queen remembered with great pleasure her visit eight years ago. The Prince Consort opened the college fifty years ago, on which occasion he was accompanied by the King, who not many years ago occupied the chair at one of these festivals, and on that occasion he got the largest collection of those days, "but I hope," continued the Prince, "to-night we shall beat that."

In proposing success to the college the Prince said he could hardly imagine a more deserving object, for all owed a debt of gratitude to the doctor who is our confidential friend from the cradle to the grave. We consult him, confide in him, trust him though he may often have disagreeable truths to tell us. There are few who have not reason to be deeply grateful for his knowledge, tender care, and patient watchfulness. His Royal Highness went on to show that it was not only individuals who were indebted to their doctors but the community as a whole reaped untold benefits from the devotion of the

profession. The school supports fifty boys on the foundation, and there are fifty aged necessitous medical men or their widows who receive a pension of £30. This side of the work requires about £8,000 a year to keep up. But the school proper is conducted as our other public schools and is self-supporting. The Prince concluded with regret that the appeal for the benevolent side was not urged by some one more eloquent, and the assurance that no one could speak with more profound conviction of of the worthiness of the claim of the Royal Medical Benevolent College on the sympathy and genorosity of all.

Lord Roseberry, as president of the college, replied and challenged any orator to vie with the pathetic, eloquent, and true terms in which His Royal Highness had spoken of the medical profession.

At the close subscriptions and donations to the amount of £6,526 were announced, including 50 guineas from the King and 100 each from the Prince and Lord Roseberry.

Princess Christian opened a bazaar on Wednesday in aid of the Royal Free Hospital and has been in attendance daily. This afternoon Princess Henry of Battenberg will formally open it, and the two princesses will pass the rest of the day in it.

Yesterday Princess Henry attended the meeting of the Colonial Nursing Association, of which she is a patroness.

On Saturday Princess Christian presided at the annual meeting of the Royal British Nurses Association, at which there was a discussion on the question of a State Registration of trained nurses.

On Thursday afternoon the King and Queen went in semi-state to the London hospital to formally open the new buildings. I say formally as they have actually been in use for about three months. This ceremony has been looked forward to and reckoned on as most important from a financial point of view, as it enables the begging which goes on to be brought to a culminating point. The new out-patient waiting hall which the King was to open was fitted up and decorated, the platform erected for the Royal party being adorned with lovely flowers and palms. Over a thousand friends of the hospital were assembled in this hall where a few days ago as many out-patients were waiting their turn to be attended to in the different departments. Consulting, dressing, and examining rooms for medical and surgical cases are attached. On the first floor are situated the obstetric, dental, aural, and massage departments; on the second floor the ophthalmic, electric, and photographic departments. Of the £80,000 which has been expended, one anonymous donor gave £25,000 on condition that (*a*) letters of admission should be abolished and (*b*) patients who could afford to do so pay something toward the cost of remedies. These conditions have been carried out, though with regard to the letter there is much discontent, and without doubt competition with the poorest general practitioners is in itself not a thing to be encouraged. This may seem a subject to pass by silently in the midst of the triumph of the management, but it forces itself on the attention of thoughtful men, and not a few believe that the money lavished on out-patients is largely wasted and ought to be devoted to in-patients. As much is true of other hospitals, but it is especially the case with this.

The venerable Duke of Cambridge, who has been president of the hospital for over fifty years, was present to welcome their majesties, who expressed their pleasure to meet him there. Addresses were presented on behalf of the committee and the staff, and in his reply the King referred to the visit of Queen Victoria and her interest in the hospital as well as to the pleasure Queen Alexandra had had in introducing the Finsen light. Their majesties then went on a tour of inspection, visiting the ophthalmic, aural, *x*-rays, electric, and Finsen rooms. They saw patients treated by *x*-rays. A demonstration of the properties of radium was also given, in which they displayed much interest. Radiographs of their hands were also taken. In the ophthalmic room the King exhibited considerable interest in a case of tobacco blindness. The Queen formally opened the Finsen department, where every lamp was in full operation and Mr. Holland informed Her Majesty that, unknown to him, the patients had collected among themselves a sum of 60 guineas as a token of their gratitude for the cure of their lupus. The Queen thanked them and afterward distributed badges to a number of the nurses who served in South Africa during the war. At the conclusion of the several ceremonies the King and Queen left the hospital in a drenching rain—such as had poured down all the way on their journey thither. It was the wettest day for a long time, but in spite of it great crowds assembled, especially in the poorer streets, determined to see and cheer for their majesties as the procession passed by.

I have exhausted my space, but not the list of various functions on behalf of the hospitals and medical charities held this week—and the coming week opens with the collection in all churches and chapels for the hospital Sunday Fund.

## LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE PLAGUE—REPRESSIVE EFFORTS OF THE BOARD OF HEALTH—RAT CATCHERS—PROPHYLACTIC INOCULATIONS—THE OPIUM TRADE—ALCOHOLIC INDULGENCE—THE FAMILY CIGAR—BETEL-NUT CHEWING.

MANILA, May 15, 1903.

IN the absence of all but a few sporadic cases of cholera in Manila, and with the increase of plague during the past few months, the Board of Health is practically devoting all its energies to the suppression of the latter disease. So far their efforts at control seem to have met with considerable success in holding down the present outbreak. In the epidemic of 1900 there were 271 cases of plague in Manila, with 199 deaths; of which 186 cases and 137 deaths occurred among the Chinese, 82 cases and 61 deaths among the Filipinos, and 3 cases with 1 death among Americans. In 1901 there were 491 cases with 432 deaths, of which 297 cases with 269 deaths occurred among the Chinese, 190 cases with 159 deaths among the Filipinos, and 2 cases were diagnosed among the Spaniards, though autopsy showed its existence in 4 Spanish cases. In the outbreak of 1902 there was a total of but 10 cases and 9 deaths, of which 4 cases and 4 deaths occurred among the Chinese and 6 cases and 5 deaths among the Filipinos. It was thought that the infection had been stamped out by the end of 1902, but either this was not the case, or, what is more probable, the city was re-infected by importation from the endemic plague centers in China. In the outbreak of the present year, up to April 26, there have been 100 cases with 84 deaths, 3 recoveries, and 13 cases, all Chinese, remaining under treatment. Of these 100 cases, 64 cases and 54 deaths occurred among the Chinese, 35 cases with 30 deaths occurred among the Filipinos, and there was 1 fatal case in an American, who died April 24, from the pneumonic form of the disease. The course of the present outbreak is as follows: January, 2 cases with 2 deaths; February, 17 cases with 14 deaths; March, 42 cases with 34 deaths; April 1-25, 39 cases with 35 deaths. Excluding the 13 cases at present under treatment, there have occurred in Manila, during the past four years, 872 cases and 724 deaths, giving a general case mortality of 83.0 per cent. The case mortality for the four years among the Chinese was 82.2 per cent., among the Filipinos 84.1 per cent., and among the few American cases 50 per cent. The greater case mortality of plague among the dark-skinned races was also well shown in the plague epidemic in Australia in 1902, in which the death rate among the Chinese attacked was about 80 per cent., while it was only about 30 per cent. among the cases occurring among whites. This lack of vital resistance to the disease is very marked. In the outbreaks in Manila the Chinese have furnished a disproportionately large number of plague cases as compared with the size of the Chinese population. Adding together the Chinese plague cases for the past four years, and considering the number of Chinese to have averaged, during that period, about 60,000, the total number of plague cases have appeared among the Chinese at the rate of 9.18 per 1,000: while the number of cases occurring during the same time among the Filipino population of Manila, about 200,000, gives a total periodic incidence of the disease of 1.5 per 1,000. The size of the white population in Manila, during these four years, has been very variable, but can probably be placed at about 20,000. At present this number is lower, owing to the recent withdrawal of troops. Figuring on a basis of 20,000, the 8 cases which have occurred in whites give a total periodic average of 0.4 per 1,000. In proportion to their numbers, the Chinese have thus been affected six times as much as the Filipinos and about twenty-three times as much as the whites. This much greater prevalence of the disease among the Chinese may depend in part upon racial susceptibility, but more upon their insanitary habits of herding together in dark, damp, dirty, and unventilated old masonry buildings, in which rats thrive and the plague bacillus finds the conditions favorable to its existence. Further, the Chinese are not cleanly in their persons and the majority wear no protection for the feet, so that bacilli from an infected dirt floor can readily gain entrance to the system through a cut or abrasion of the lower extremities. Post-mortem examinations show that the infection occurs in this manner in the great majority of instances. The lower-class Filipinos also go barefooted; but they do not generally live in the solid masonry buildings preferred by the Chinese, but live in their houses of nipa and bamboo, raised well above the ground and open to light and air. Rats find few congenial lurking places in such houses, particularly when the house

has an iron roof instead of a nipa thatch, and the local conditions are not favorable for the continued existence of the plague bacillus. In many instances in which the disease attacks Filipinos, it is probable that the infection has taken place elsewhere than in the houses of the latter. It is the poorer class, of both the Chinese and Filipinos, that is commonly attacked The type of the disease among the Chinese is usually the bubonic form, and the femoral or inguinal glands are most commonly the ones involved. The glands of the neck or axilla are only rarely affected. But very few cases of the septicæmic type occur. The primary pneumonic form is rare, except toward the end of an outbreak, but post-mortem examination shows secondary infection of the lungs in many cases The primary pneumonic form is the type which is usually present when whites or natives of the better class are attacked. The American who died recently presented this form. The wearing of shoes, stockings, and long trousers, with avoidance of the insanitary and infected districts, does much to protect the white population. The health authorities are inclined to regard the bubonic type of the disease as not highly contagious, and a sick plague rat gives rise to more apprehension than a case of the bubonic form in a human being. The septicæmic form is regarded as more contagious, and the pneumonic form as very dangerous. The disease seems to be readily propagated from rat to rat and from rat to man, but rarely from man to man, except by inoculation. None of the nurses or physicians in charge of plague cases have contracted the disease. Of 206 plague contacts quarantined this year at the detention camp, only 6, or about 3 per cent., subsequently developed the disease; and of these six cases three developed within four days after admission, and were very likely contracted from the same source of infection from which the first sick person contracted his own disease, rather than from that sick person himself. It is the exception for more than one case to occur in a house, as the health authorities are vigorously handling the plague proposition. As a result of past experience, the plague contacts are not regarded at present as such a menace to the public health as they have been considered in previous outbreaks. In the present outbreak, plague has appeared in every district of the city except the Paco district, and sporadic cases have occurred even in the best residential sections. These cases, however, were very probably infected in the less sanitary quarters of the city, where plague is prevalent. There seems to have been no spread of the disease from these sporadic cases. It is in the Chinese quarters of the Binondo and San Nicolas districts that the disease is most prevalent, and it is from these districts that the infection is every little while carried out into other more sanitary parts of the city, where the case develops. San Nicolas lies along the Pasig River, and, like Binondo, is almost solidly built up with old insanitary Spanish buildings, built to withstand time and earthquakes, and without provision for light and ventilation. There are few sanitary conveniences, the floors are largely of dirt, incorporated by naked feet with the filth of three centuries, and no amount of ordinary cleaning will place them in a sanitary condition. They are constantly being repaired and improved, but can never be made satisfactorily sanitary. The city has no funds to pay for their condemnation and destruction, they will not burn down, and after resisting the earthquakes of centuries, nothing less than a charge of dynamite would seem to have an effect on their massive walls. Such houses are a thorn in the side of the Board of Health, and, unfortunately, seem destined to remain such for some time to come. It is in the buildings of this character, occupied by the Chinese, that the disease has so far been able to resist the efforts of the health authorities to stamp it out.

The general efforts of the Board of Health against plague have been directed toward rat destruction and securing cleanliness and improvement of houses, particularly in the infected districts. There are about 100 official rat-catchers employed by the Board of Health, who are paid a salary and also given a bonus for each rat delivered at a health station. There is also a standing bounty on rats to be paid to the general public. The official rat-catchers utilize about 2,000 traps and put out a great deal of poison. They also kill many rats by exploring old drains, etc., with their hands, and driving the rats out of holes, etc., with sulphur blowers. They bring in about 500 rats daily; besides which a number are killed by poison and are not found, and many are trapped and destroyed by the citizens. Recently the Board of Health issued a circular requesting the coöperation of the public in this respect, and has loaned a large number of traps for this purpose. Poison is not found to be very effective, in spite of frequent change of the bates and poison, as the rats soon get educated as to their nature and carefully avoid them. Strychnine, arsenic, and powdered glass are used, mixed with prepared compound baits in which bacon, flour, meal, potatoes, eggs, rice, etc., are among the ingredients. These baits are put out at night and carefully collected in the morning, small dishes being used for that purpose. Each rat-catcher can handle about 30 traps and 100 plates of poisoned bait, besides killing many rats with his hands and sticks. The Board of Health has ordered a number of trained rat-catching ferrets from Australia to assist the rat-catchers in their work, but they have not as yet arrived. The marine hospital surgeons are also greatly aiding the Board of Health in its work of rat destruction, as the quarantine officials have undertaken to destroy the rats by sulphur fumigation, on all the vessels entering the Pasig River, both on arrival and departure. This is to prevent the importation of plague rats from infected ports, or the transportation to other ports in the archipelago of such rats which might get on board while the vessel is lying at Manila. Large vessels which load and unload by lighters in the harbor, except such as are returning to the United States, are not fumigated regularly, as it is thought that, when the cargo is handled in this way, there will be little opportunity for rats to get to and from the shore. The quarantine officials estimate that about thirty-five tons of sulphur will be required to carry out this work of rat destruction on board ship. Large numbers of rats are killed in this way. All rats killed on ship and shore are tagged with the place, or street and number, at which killed, sent to the government laboratory and examined for plague, but only a small proportion are found to be affected; this, however, is what might be expected, as plague is soon fatal to rats, and only a small part of the rodent community, like the human population, is affected at any one time. An unavoidable drawback to the efficiency of the work of rat-catching is that the rats which are sick with plague, and which it is most important to catch, have little desire for food and are not tempted to enter traps or partake of poisoned baits. With the instinct common to dying animals, such rats seek dark holes where it is difficult to secure them, alive or dead. The board of health goes on the principle, however, that the destruction of healthy rats has a positive sanitary value, as it removes a susceptible animal, which may later contract the disease and assist in its further spread.

The special measures carried out by the Board of Health include a system of house-to-house inspection, prompt notification of the district medical inspectors of the existence of any case resembling plague or other infectious disease, and prompt removal of the plague case or suspect to the plague hospital and isolation camp. The dead are sent to the morgue. All persons who have been in contact with the plague case are sent to the detention camp, where they are bathed, their clothing disinfected, and they are given an inoculation of Shiga's antipestic serum. These prophylactic inoculations with antipestic serum are also being generally carried on among the Chinese in the infected districts; all rats in the infected houses are then exterminated. When practicable, the house or group of houses is first enclosed by a portable fence, and all drains or other means of escape are closed. The entire rat-catching gang of the district is then concentrated within the enclosure, and if necessary, this force is supplemented from other districts. All possible retreats for rats, as drains, double walls, cesspools, piles of wood, etc., are then carefully explored, and sulphur dioxide fumes are forced into the rat holes and burrows. Piles of refuse are opened up and removed, floor and side boards, bricks or tiling, are raised when necessary to get at the rats. In one plague house four live, and six dead rats were in this way found under a single floor. After the rat-catchers have performed their work, tightly built houses are sealed up and fumigated with sulphur to kill any remaining rats, and also all fleas and insect vermin. Houses with nipa roofs have sulphur burned in them to drive out any rats which may have taken refuge in the thatch. Nipa houses in poor repair are condemned and burned. When the houses cannot be enclosed by the portable fence, the avenues of escape are blocked as well as possible and the same measures carried out. The rat-catchers then proceed to adjacent houses or buildings to which the rats from the infected house are liable to have resorted, and treat them in the same manner. The house is then disinfected throughout with 5 per cent. carbolic-acid solution; walls, floors, and furniture are sprayed or mopped with this solution. Dirt floors are sprayed with the solution, and then milk of lime is applied in an even coat with a broom over the whole surface. This coating of lime is allowed to remain for at least twelve hours. Fabrics are disinfected by steam, solutions, formaldehyde, or sulphur. After disinfection, the building is cleaned, repaired, and made rat-proof. Cement floors are put in, and rat holes stopped with cement mixed with broken glass or with strips of tin. All drains, cesspools, closets, etc., are put in good sanitary condition. Walls and woodwork are whitewashed or repainted.

After the house has been thus treated, the contacts are allowed to return and resume business, but they are infected by a medical inspector daily, for a period of nine days, dating from their removal to the detention camp. Houses in which plague rats have been captured, but in which no cases of the disease have occurred among human beings are treated in the same way as if a case of human plague had occurred, except that the occupants are not removed to the detention camp. By these measures the disease has, during the past month, been held down and prevented from increasing to the degree which might have been expected from the course of previous epidemics. These strict measures do not meet with the favor of the Chinese and Filipinos, but no serious opposition on their part is expected. There has been some complaint that the Chinese occupants of houses have sprung the rat-traps and thrown away the poisoned baits left on their premises, lest plague rats be killed and their houses be subjected to disinfection, but this tendency has been met by the appointment of Chinese rat-catchers, whose pay depends in large degree upon the number of rats caught, and who would complain to the Chinese head men in case of interference with their work and remuneration.

## LETTER FROM NEW ZEALAND.

(From Our Special Correspondent.)

AUCKLAND, May 20, 1903.

THE arrival of one of your men-of-war, the *Wheeling*, has been one of the principal events to enliven our dull colonial life. She has come in for repairs to her boilers, and also to give the crew a change of climate. They were beginning to suffer in health from a long spell among the South Sea Islands, and looked very anæmic when they arrived. I made the acquaintance of the ship's surgeon, Dr. Raymond Spear, who has, I understand, done very good work in Samoa. He is taking advantage of his stay here to attend the operations at the Auckland Hospital.

There is a very lively discussion going on here about the cost of the hospital, which has increased about 50 per cent. during the last two or three years. The number of in-patients during the year 1902-3 (from April 1, 1902, to March 31, 1903) was 2,098, there having been, in the hospital on April 1, 1902, 203, admitted during the year 1895, and remaining on April 12, 1903, 149. Number discharged, 1,717; deaths, 232. The total cost of maintenance was £15,661 (say, $78,305). Average daily number of patients, 190.2; average days stay of patients, 33; average cost per day 4s. 7¾d. ($1.12). But the gross total includes the cost of medicines and dressings for out-patients. It is evident, from the average stay in hospital, thirty-three days, that a considerable proportion of the patients must be chronic cases, and this is borne out by the appearance of the wards. About a thousand operations were performed last year. Of course these largely increase the expenses, as everything is done under strictly antiseptic or aseptic conditions.

Now, the first thing that a man of the old school remarks is that, with all these wonderful improvements in medicine and surgery, the new school has not lessened the rate of mortality. Eleven point 5 per cent. (11.5) is no better than the average mortality of London hospitals forty or fifty years ago. How is this? Of course, numbers of cases are operated on which would have been allowed to die quickly in the old days, but *cui bono?* I have just examined a lady of forty-six years who has had the abdomen opened three times—once for floating kidney (which is still floating, by the way, and quite perceptible), and twice for uterine or ovarian trouble. On one occasion something went wrong with the stitches, and the wound remained unhealed for five months. Some further operation was then performed, and the stitches, she thinks, were removed. She is now suffering from pain in the cicatrix, and from a much enlarged and nodulated cervix, which, to me, feels highly suspicious. In addition to the laparotomies, she has had the uterus "scraped" and lacerations of the cervix operated on. She wore pessaries for a long time. As she is an American, I trust that the sympathies of your readers will be aroused. This is, I admit, an extreme case, but similar cases are very frequent—much more so than some of the operators would believe.

One of the complaints against the Auckland Hospital is the enormous drug bill, £2,317. This is equal to $222 a week. Another heavy item is that for nurses. How much they cost in salaries the published accounts do not show, as the item salaries (£4,066) does not distinguish between the salaries of nurses, servants, and doctors. There are sixty-one nurses, and the maintenance of their home costs £1,430 a year. Their uniform, in addition, costs £160. All this is in addition to interest on the building they occupy, and the cost of repairs, furniture, ironmongery, bedding, washing, fuel, gas, water supply (£223), and sundries.

I give these particulars because it may interest some of your readers to see what a hospital costs in the most expensive part of the British dominions. We have a unique example of disinterestedness in the Senior Resident Medical Officer, who has actually refused an increase of salary! And he is an Irishman! I have already prepared a short obituary of him, and an inscription for his tombstone, as I feel convinced he cannot live long.

We are undergoing one of our periodical smallpox scares. Two or three passengers have been landed and placed in quarantine. The population refuses to be agitated. We have had so many of such cases, and nothing more comes of them. Is there something antagonistic to smallpox in this climate? The population is not well vaccinated, so that if it did take a footing here we should have a pretty severe epidemic. If it got amongst the Maories it would cause a fearful mortality.

Since writing the above it is announced that scarlatina has broken out in the Auckland Hospital in two patients. No visitors are permitted in the hospital. I expect that there will be no operations except such as are absolutely necessary.

The Public Health Department has set itself in such direct opposition to public opinion by its demand for infectious disease hospitals all over the colony, that, in all probability, the next session of Parliament will see the department deprived of some of its powers. The very energetic and talented chief medical officer of health seems to forget that, with an annual death rate of only ten or eleven per thousand, it is impossible to convince people of the necessity for perfect isolation. They are willing to send cases from overcrowded houses to hospital, but they kick at having to build an entirely new hospital with medical staff, nurses, servants, etc., and all the contingent expenses.

A very useful reform in the diet of the people of the colony will be effected by the enormous increase in the price of meat, which has risen about 100 per cent. in less than a year. Hitherto, it has been the general colonial fashion to have meat three times a day. And when good mutton or beef could be had at from twopence to threepence a pound, it was the cheapest and most satisfying food. But now that prime joints are from sixpence to eightpence, the consumption, I am informed, has greatly diminished.

A great deal of gout and skin disease was caused by this excessive meat eating. A certain class of people are always declaiming about the disease produced by alcohol. My experience in New Zealand is that for one case of disease arising from the consumption of alcohol there are twenty at least caused by excessive tea drinking, meat eating, and tobacco smoking.

In addition, general inoculation of the Chinese population is being carried on with Shiga's antipestic prophylactic serum, the work being done gratuitously by the board-of-health physicians. Some of the Chinese prefer to employ their own private physicians—Americans and Filipinos, who in such case secure the serum from the government laboratories. So far about 2,000 inoculations have been made, and it is hoped that the entire number of inoculations required will be completed in about a month. There has been some disinclination on the part of the Chinese to submit to the inoculation, as rumors circulated among them that the Americans were injecting poison into them. It so happened, however, that several cases occurred in rapid succession, in which the only uninoculated Chinaman in a house was attacked with plague, while those who had been inoculated escaped. The Chinese soon heard of these instances, and their opposition to inoculation has largely disappeared. There have been no untoward effects as a result of the inoculations already made. All the serum is carefully prepared, and each lot is tested on monkeys before being sent out from the laboratory. It has been found that the Shiga prophylactic serum gives somewhat better results than that of Haffkine. It is made by cultivating the plague bacillus on agar, scraping off the colonies, weighing them, mixing them with normal saline solution in such proportion that one cubic centimeter of salt-solution contains 6 milligrams and then sterilizing at 60° C. for half an hour. The dose is one cubic centimeter, which confers an immunity for about a year. The curative serum is employed when a case of plague has actually developed, as the prophylactic serum seems to affect the patient very unfavorably under such conditions, and lowers his powers of vital resistance.

The question of turning over the opium trade of the islands to a single firm, as a concession, is now being considered by the commission, and several Chinese firms are endeavoring to secure the monopoly. It is estimated that about 60 per cent. of the Chinese in the islands habitually use the drug, but the Chinese who are endeavor-

ing to secure the monopoly claim that only about half of 1 per cent. smoke opium to excess. The latter is undoubtedly too small a proportion, though the evils of opium smoking seem to be surprisingly small when the great use of the drug is considered. The Chinese claim that the use of opium is a positive necessity to many, and have the most extravagant ideas as to its value in protecting the user against cholera, plague, and other diseases. After a hard day's work the Chinaman resorts to the opium pipe as naturally as the white seeks tobacco or alcoholic stimulation, and apparently with no worse effects, on the whole. Certainly, as far as order and keeping the peace is concerned, the use of opium is preferable to that of alcohol. The Chinaman who smokes "hop" minds his own business, interferes with no one, creates no disturbance, and commits no breach of the peace. He rarely smokes until after working hours, and, excepting in rare cases, his industry and productiveness seem to be little, if at all, impaired. The Chinese say that with the moderate use of opium more work can be performed with than without its stimulus. Here there seems to be little of that wholesale decay and degeneration which is said to follow its use in many districts in China. It is claimed by some that the Filipinos are beginning to acquire a liking for the use of opium, but this does not seem to be the case. The worst part of the whole matter, from a sanitary standpoint, seems to be found in the insanitary condition of the opium joints, of which there are many in the Chinese districts of Manila. Lately, the health authorities have been giving much attention to this point, with the result that the opium dens have been cleaned up and put in much better sanitary condition.

The Chinese rarely use alcoholics in any form, and the Filipinos are extremely moderate in their use. The latter use the "bino" distilled from the nipa palm; which, in the large quantities used by our soldiers, has such baleful effects. The foreigner attempts to use "bino," however, as he would use whiskey, or even beer, while the native is very absteminous and is quite satisfied with two or three thimblefuls. Cases of drunkenness, except among the Americans and other whites, here are therefore very rare, and our failing in this respect has done much to lower us as a race, in the eyes of the natives. The abolition of the canteen has unquestionably increased drunkenness among the soldiers in the islands, and it remains to be seen how much effect the new law prohibiting the sale of liquors within two miles of a number of military posts will have upon army morals. There would seem to be no doubt but that the too great use of alcoholics in the tropics has effects which are more certain, rapid, and marked than result from similar use in cooler climates. As the climate is hot and enervating, anything which is stimulating, cold, and wet is very grateful, and its use may unconsciously be carried to greater excess than would be the case in a cooler and more bracing climate.

With regard to tobacco, its use is universal, and the native child acquires the tobacco habit as soon as it is able to walk. In the northern provinces especially, it is no uncommon sight to see a child five or six years old puffing vigorously at a big cigar. The women smoke fully as much as the men, and commonly smoke cigars where the men use cigarettes. Pipes are rarely used, and the chewing of tobacco is unheard of. In the northern parts of Luzon, particularly in the great tobacco-growing district of the Cagayan Valley, immense cigars, often a couple of feet long and as thick as the wrist, are used. Such a cigar is rolled by one of the household, suspended from a rafter of the house by a string, and smoked during the day by all the members of the family as desired. Fortunately the tobacco of the Philippines is very mild, but the "rankness" of the last few inches of such a giant cigar can well be imagined. Some have claimed that the universal use of tobacco is a strong factor in determining the small stature of the Filipinos, but there would seem to be little basis for such a claim. The evil effects of nicotine so often seen in the United States as a result of the excessive use of tobacco are not seen here. The Chinese smoke tobacco to a large extent, but by no means as much as the Filipinos. It is said that in China and Japan a tremendous demand has sprung up for American cigarettes during the last few years, as a result of the efforts of American firms. It is interesting to note that the cheap brands of cigarettes made from American tobacco are sold in Japan and China at about half the price charged for the same cigarettes in the United States.

In lieu of chewing tobacco, the natives chew betel nut, mixed with powdered lime. This gives the saliva a red coloration like blood, and this bloody appearance of the mouth renders the user very disgusting to foreign eyes. The natives claim that the use of betal nut aids digestion, but the better class of Filipino doctors say that it has quite the opposite effect, as might be expected.

Coffee is used very little by the natives, though plenty of it is raised for export. Tea is not used at all, except by the Chinese, who use it as their habitual beverage. The natives have no "drug habits" such as are met with in civilized communities, and cocaine, chloral, and other drug "fiends" are unknown here.

## Progress of Medical Science.

*Journal of the American Medical Association, June 27, 1903.*

**The Treatment of Vascular Tumors by the Injection of Water at a High Temperature.**—J. A. Wyeth discusses this procedure with reference to its employment in tubercular adenitis, abscess, fistulous tracts, etc. From animal experimentation he became convinced that with injections of boiling water, coagulation of the blood and albuminoids in vascular neoplasms was possible. Clinical experience has convinced him of the value of the method. He gives the histories of three cases thus treated. Case 1 was a large, cavernous nævus occupying the right lower jaw and chin, and a portion of the neck below, of a girl of twenty years. Case 2 was of a similar nature, the site of the swelling being on the back just above the right shoulder blade of a girl of nine years. Case 3 was a small pulsating tumor in a branch of the temporal artery directly over the ear. Allusion is also made to the application of the method in several cases of capillary angioma. In cases presenting tumors of any size, general anæsthesia is advised. The body or part operated on should be held firmly and an assistant should hold a sponge saturated with cold water over the needle, in order to prevent scalding of the skin should the apparatus leak. A small hypodermic needle is used, and this should be thrust through the sound skin, about one-eighth of an inch from the edge of the angioma, pushed beneath the neoplasm, care being taken not to let the point come through the surface. From five to fifteen minims of water may be injected in one spot, changing the needle here and there to suit the size of the mass. When the injections are made directly into the enlarged capillaries, necrosis almost always occurs, but if the water is forced well beneath the surface, the deeper parent vessels will be coagulated, causing the nævus to disappear by gradual denutrition (granular metamorphosis). It is a wise precaution to cover the area injected at once with aseptic collodion to prevent infection. This operation may be repeated from time to time until a cure is effected.

**A Clinical Report of a Case of Blastomycosis of the Skin from Accidental Inoculation.**—The patient of Newton Evans was a physician aged twenty-eight years, who inoculated himself on the finger at an autopsy made on a patient dying from systemic blastomycetic infection. The general features of a pus finger soon appeared with ensuing involvment of the arm. Incision and curetting of the finger removed a fungous mass extending down to the tendons. The wound was packed and allowed to heal in the usual way. During healing there was a slight febrile reaction, and after a crust had formed over the incised surface it was noted that little pustules were forming around and beneath the edges of the crust. These were evacuated. The tenderness was not marked. There also formed on the back of the hand in the subcutaneous tissue, over the metacarpal bone of the index finger, a small nodule of the size of a split pea, at first hard and later softened. This was not painful. It remained for from six to eight weeks, gradually growing smaller and disappeared. Simultaneously with the appearance of this nodule, a somewhat similar nodule appeared on the palmer surface of the affected finger, about one-half an inch above the lesion. This lesion contained a very small pus cavity, just beneath the epidermis, which was evacuated a number of times and decreased in size, but was not entirely healed at the time the case was reported. The granulation tissue removed by the curetting showed very little remaining epithelium on the surface, a mass of necrotic tissue occupying its place. Beneath the epidermis the corium was filled with a dense cellular exudate, for the most part consisting of polynuclear leucocytes. Scattered about in this tissue were found numbers of the typical, doubly-contoured, budding organisms, exactly identical in appearance to the organisms found in immense numbers in the case on which an autopsy was performed and from which the disease presumably was contracted. The paper closes with general considerations on blastomycetic infection.

*Medical News. June 27, 1903.*

**Report of a Case of Stammering and Method of Treatment.**—James Moreau Brown reports the case of a Russian who could speak only the Hebrew language. He was first taught to breathe deeply from the diaphragm, with frequent intervals of rest. Later came breathing exercises consisting in raising the arms slowly above the

head with inspiration, and lowering them upon expiration. The breath was held with firmness and released with energy. Slow speech was taught, with assurance, and when the patient was embarrassed, more attention was given to slowness and deliberation. Cold sponging of the upper part of the body daily, with careful attention to the general health and hygienic surroundings, were insisted upon. Exercises were given for strengthening the muscles of the tongue and lips, with the teeth overlapping and held firmly together. At first letters were practised, then words, and finally sentences were articulated with perfect ease. Breathing is most beneficial in difficulties of speech and a very important auxiliary in the treatment.

**Poisoning by Corrosives.**—Eli H. Long says that by corrosive action is meant that immediate disorganization or coagulation of tissue that occurs upon contact with poison. Nearly all corrosives are strong chemicals. The fact and the nature of their destructive action depend upon their chemical affinities. The severity of action depends upon concentration rather than upon quantity. Leaving out the halogens and arsenic, the following groups of corrosives may be considered: Mineral acids, caustic alkalies, coagulants. The mineral acids all coagulate albumin in addition to their affinity for bases. The caustic alkalies, by reason of their common affinities for water and acids, act similarly. They do not coagulate albumin. The coagulant corrosives act differently according to the affinities presented by each. Carbolic acid possesses the simple affinity for albumin, while the metallic compounds, when decomposed, have also the action of the liberated acid in addition to the coagulant action. The employment of a chemical antidote is most important, but even more important it is to dilute the poison largely by a copious draft of water without reference to the character of the poison. Corresponding closely to the three groups of poisons under consideration, the chief antidotes of practical value are: Dilute alkalies, dilute acids, albuminous substances. After administering the chemical antidote, emesis should be favored, unless already excessive, by copious drafts of warm water. When the poison has been removed, demulcents should be employed to soothe the corroded tissues, and they should be left in the stomach to prevent further damage to its walls by friction.

*New York Medical Journal, June 27, 1903.*

**The Ignition of Ether Vapor in Presence of a Closed Electric Light.**—D. H. Murray relates that during one of his operations the anesthetist unable to see the patient's eyes clearly (the patient being prone) turned on the electric light. Instantly there was a sudden flash, and it was found that the ether vapor had ignited. Fortunately only a slight scorching of the patient's hair and eyebrows and a superficial burn on the forehead resulted. Murray has never heard of such an accident before, and found himself unable to reproduce experimentally the untoward result, though he tried several times with the same burner and under conditions identical with those of his operation so far as the ether and light were concerned. He cautions against turning on electric lights near the vapor of ether, especially when the room is small and the ether vapor dense.

**Prophylactic Injections of Tetanus Antitoxin in Cases of Wounds from Toy Pistols.**—F. L. Taylor has seen in hospital practice 129 cases of wounds from toy pistols during the past three years. Of this number but one case developed tetanus. Counting cases previously reported, prophylactic injections were used in seventy-two patients while fifty-seven did not get them. No injection was given in the fatal case mentioned above. The author recognizes the limitation of any conclusions to be drawn from these figures. He nevertheless states that it is his practice to inject in all cases in which the wound has not been thoroughly open and cleaned within a short time after its infliction. He opens all wounds freely, incises them deeply and curettes them thoroughly. He then swabs them out with pure carbolic, its action being limited, when deemed necessary, with alcohol. The amount of serum to be used is 10 c.c., and the injection may be repeated in three or four days. The same pains in the joints and rashes that sometimes follow the exhibition of the antitoxin of diphtheria may occur after the use of tetanus antitoxin; they are transitory, and usually cause but slight inconvenience.

**The Application of Hospital Methods for the Prevention and Treatment of Puerperal Sepsis to Private Practice.**—From the statistics of the New York City Health Department W. S. Stone found that out of 178,139 births in five years, there was a mortalty rate from puerperal infection of 1 in 360, or about .27 per cent. From the out-door service of the Lying-in-Hospital, out of 10,234 births in 1897, the rate was .14 per cent. He goes on to state that asepsis instead of antisepsis is the great principle of obstetric as well as of surgical practice, and this is accomplished by the application of the following rules: (1) The use of no antepartum douches, except there is present for example, a purulent discharge, in order to protect the baby's eyes from gonorrhœal infection; not, however, as curative, because the seat of the infection is in the cervical mucosa; (2) the sterilization of the patient's external genitals and the attendant's hands; (3) the use of no postpartum douches, unless there is some special indication. He dwells at some length on the rules laid down for students in the out-door service in their conduct of obstetric cases. These do not differ except in minor details from those in vogue at sister institutions. He has used rubber gloves with the greatest satisfaction, and believes that from their general introduction the morbidity from puerperal infection can be reduced at least one-half. He does not believe that any evidence has thus far been presented that any form of specific treatment is of the least value in those severe types of puerperal infection designated as septicæmia or pyæmia.

*American Medicine, June 27, 1903.*

**The Relation of Neuralgic Headaches to Storms.**—S Weir Mitchell states that the originating causes of hemicrania are as yet unknown. The determining causes of the separate attacks have never yet been made clear enough to enable the victims to avoid them by precautionary measures. Eyestrains are rarely the primary trouble, but may add to the number and exaggerate the force of attacks. Freedom from exhaustion of mind and body is most apt to lessen the number of headaches. It is very probable that atmospheric conditions play an important part in the production of this form of pain. Certain migraines are due to storms, but not, as a rule, to the summer electric storms, which, nevertheless, in some hysterical women are sure to occasion a general headache, distinct in character from hemicranial attacks. The writer presents a chart on which are drawn two curves, the one representing the storm curve, the other the headache curve. March and April are the worst months and October and February the best. There is among later writers a quite general belief that the storm winds favor the production of headaches.

**Chronic Cyanotic Polycythæmia, with Notes upon Two Cases.**—T. N. Hall presents this interesting report. He offers this title as a "tentative designation for certain cases recently reported of chronic cyanosis with immense increase in the number of red cells and without cardiac disease. The first patient was a woman, aged sixty-one years. Since the menopause she suffered from dyspnœa and palpitation. The most striking feature in her appearance was the cyanosis which was startling in its intensity. Over her face were tortuous veins, almost black, and 2 to 4 mm. in width. The abdominal walls were so thick that examination of the spleen was very difficult. It was certainly not greatly enlarged. The abdominal examination was otherwise negative. As to the blood examination, the drop obtained by puncture was extremely dark in color, and coagulated so quickly that it could scarcely be removed from the capillary tube for the blood count. The red cells numbered 9,940,600, and were normal in character. The leucocytes numbered 6,500 and were normal in variety and proportion. The hæmoglobin was estimated at the first examination at 170, and at the second, 200. The blood had to be diluted twice as much as usual before making the estimation. The second patient was a woman of forty years. There were very large and dark veins upon the face, many being 2 mm. or 3 mm. in width. The blood was so thick it would hardly flow. The spleen was greatly enlarged. The notes of this last case were obtained from Turk. He laid special emphasis in these cases upon three features: the polycythæmia, the dilated veins, and the enlarged veins. Other manifestations have been observed in different cases. In the first one reported here, dyspnœa and palpitation were more striking than in the other two quoted. In the report of the autopsy on Cabot's case there seemed to be nothing characteristic but the marked passive congestion of all the internal organs. There were neurotic manifestations in Turk's and Cabot's cases. In the writer's case there was a well-defined chronic nephritis with cardiac manifestations. A French writer found tuberculosis of the spleen in one of these cases post mortem. The writer believes that all these cases should be put on record for collective study.

*The Lancet, June 20, 1903.*

**Note on an Outbreak of Malaria on Board Ship.**—J. Bell mentions the experience of members of warship crews who went ashore at certain Asiatic ports and who, some thirteen days later, when at sea came down with malaria. The correctness of the diagnosis was confirmed by the finding in each case of the malarial parasite. The majority were of the malignant type while a few were of the

tertian variety. All the patients recovered under quinine. No mosquitos were noticed on the boats.

**Two Fatal Cases of Partial Thyroidectomy.**—The cases are reported by F. C. Madden, one patient being an Egyptian girl of twelve years. Death resulted from insufficiency of thyroid secretion, the immediate factor being a post-operative tetany of the respiratory muscles. In its earlier stages this tetany resembled hysteria, but later the spasms became so severe as to suggest tetanus. At the autopsy no trace of thyroid tissue could be found in the neck, and it was obvious that a small piece left at the time of operation had atrophied. The author believes that in such cases thyroid medication should be pushed to the limit of safety. The other case was that of a blind Egyptian man, aged twenty-four years. In this case death resulted from excessive absorption of thyroid secretion. The symptoms were not those of collapse, but were exactly similar to those observed when the administration of thyroid extract has been pushed to an extreme degree. It was supposed that there was a sudden absorption into the system of the thyroid secretion from the cut surfaces of the isthmus, the extreme vascularity of the parts accounting for the rapidity of absorption.

**Preliminary Note on the Use of Chloroform in the Preparation of Vaccine.**—A. B. Green calls attention to the fact that the action of glycerin on vaccine eliminates the extraneous bacteria in the course of a few weeks. He finds that a solution of chloroform in distilled water will accomplish the same result in from one to six hours. He uses a solution of one to two hundred. His method is described in full, and for it he claims the following advantages: (1) So speedy an elimination of extraneous microorganisms is attained that vaccine, practically free from such organisms, can be distributed for use within a few hours of its collection from the calf. In times of urgent demand for large quantities of vaccine, such as occur during smallpox epidemics, this process must needs prove of great value, since the necessity for wasting some weeks for elimination of extraneous organisms by glycerin will be done away with. (2) In so far as the vaccination value of vaccine depends on the activity of a living organism deterioration of that value must occur in the course of a longer or shorter time. The potency of some vaccines, glycerinated or otherwise, becomes greatly impaired within a few weeks of collection—that is, within the time required for glycerin to exert fully its influence in eliminating extraneous organisms. Some of these vaccines may, at the time of their collection, have possessed a high vaccination value. Vaccine, characterized by this high but somewhat transient potency, can by means of the chloroform process be used at once before its activity has deteriorated, thus allowing greater economy of vaccine material than would otherwise be possible. (3) For a similar reason the chloroform process might be of considerable use in hot climates where the preservation of the potency of vaccine is frequently a matter of considerable difficulty

**On the Dangers of Railway Trips to High Altitudes, Especially for Elderly People.**—T. Zangger utters a word of warning against the dangers resulting from mountain ascents above an altitude of 3,300 feet. These are apoplexy and heart failure of thrombosis of the heart and embolus of the lung. The attacks may come on even two or three days after the patient has descended to the usual level. Patients with arteriosclerosis should avoid high altitudes, and the danger is not entirely avoided even if the ascent is made by train instead of on foot. The so-called "mountain sickness" of explorers who often go up 10,000 feet or more is not only accompanied but is produced by slight dilatation of the right cardiac ventricle. Elderly people should always submit to a medical examination before making a mountain ascent. Not only is there an alteration in barometric pressure, but the chemical features of respiration also change. The oxygen absorbed lessens while the respiratory quotient rises. The consequent increase of carbonic acid in the blood must also act to the detriment of a feeble dilated heart. The heart rate increases, there is a rapid variation of the temperature of the atmosphere. and peripheral blood vessels contract. Such vasomotor changes must affect the blood-pressure and the distribution of the blood in the whole system, even as far as the heart. It can be easily understood that on the return to the low ground considerable oscillations of the blood-pressure, and perhaps a considerable rise of some duration, may take place—a sequence of events which may explain the sudden occurrence of apoplexy. It must be remembered that the vessels of the brain have not yet been proved to possess vasomotor nerves, so that just at the most vital centers of life the regulation of the blood-pressure may be very inconsiderable or even altogether wanting. It is therefore not surprising that a feeble heart should show insufficiency under such an unusual strain.

*British Medical Journal, June 20, 1903.*

**Rectal Serum Therapy.**—J. Porter Parkinson states that for the last two years the rectal use of serums has been in constant use at the London Temperance Hospital. The results have been excellent in the case of anti-diphtherial serum, but antistreptococcus serum by rectal injection has shown the same uncertainty of effect that it does when administered by the subcutaneous method. Its rectal injection is free, however, from the disadvantages and dangers which may attend the subcutaneous method, such as local abscesses, etc., and thus may be preferred, as there seems no doubt that it is rapidly absorbed.

**The Duration of Life after Gastrostomy for Cancer of the Œsophagus.**—Frederick Treves cites the case of a patient upon whom he performed gastrostomy. There was a cancerous growth involving the termination of the gullet and extending to the stomach. The disease reached nearly the whole length of the lesser curvature of the stomach. The œsophageal opening was practically closed. There were no secondary deposits visible in the liver. The patient lived for three years less one month. He was practically free from pain throughout his long illness, and never suffered in the least from the gastrostomy wound.

On January 28 she did not recognize anyone or understand anything. Just below each mastoid she was very tender to pressure. There was no discharge from the nose or the mouth. It was thought that the most probable diagnosis was that of cerebral abscess. On January 31 her eyes were deviated to the right and upward, axes parallel. She could look in any direction and there was no oculomotor paralysis or nystagmus. The discs were normal. On the same day she had a Jacksonian convulsion. On February 2 the eyes were divergent, both being turned outward. She died on February 3 without regaining consciousness or having any more fits. Necropsy, which was limited to the brain, showed the pia arachnoid at the base of the brain in front of the optic chiasma to be injected and studded with small tubercles, especially along the sylvian fissure on the left side; there was no lymph exuded, no matting, and no excess of fluid. The only symptom in this case which did not fit in with the diagnosis of cerebral abscess, on the left side, was the conjugate deviation of the eyes.

**Case of Tuberculous Meningitis in an Adult, with Unusual Symptoms.**—T. H. Morse and A. J. Cleveland report this case, which is interesting on account of the unusual and misleading nature of the symptoms, together with the fact that the disease ran a very acute course when there was no reason to suspect any primary tuberculous lesion. The patient, a woman of forty years, was operated on in November, an abscess in connection with the left ovary and tube being dissected out. The abscess was, apparently, of long standing and its cause was not obvious. There was nothing about the patient suggesting a tuberculous process. On January 1 she suffered from sickness and diarrhœa, ascribed to an error in diet. On January 20 she suffered from very intense headache, which was not referred to any particular part of the head. This condition lasted for a week. Her pulse was nearly always 64, and the temperature, as a rule, 97.8°. Her mind was clear and there was no paralysis; the pupils were equal and active and the knee-jerks normal. On January 27 she constantly misused and misplaced words. She was given gas and ether and had two teeth removed.

*Berliner klinische Wochenschrift, June 8, 1903.*

**A Case of Severe Intestinal Autointoxication.**—Stuertz reports a case which is of interest because of the pronounced nervous symptoms present and also because of a marked brachycardia which succeeded the attack, and persisted for twelve days thereafter, the frequency of the pulse being repeatedly reduced to 42 per minute. The patient was a female, seventeen years of age, and gave no previous history of intestinal or nervous disturbances. The attack followed the copious ingestion of raspberries and green beans, and was ushered in by violent vomiting and severe abdominal pains. Constipation had been previously present. Severe nervous symptoms, consisting of muscular twitchings, hallucinations, loss of consciousness, and finally coma soon developed. Throughout the acute attack the temperature was only slightly above normal, the pulse not going above 72. The acute symptoms were promptly and completely relieved by the administration of calomel and high enema.

**The Physiologico-pathological Importance of the Radium Rays.**—E. S. London gives a preliminary report of his researches. His studies were conducted with 30 mg. of pure radium bromide inclosed in a box made of gutta percha and metal. (1) If a piece of sealing wax is actively rubbed with flannel it will, as is well known, attract to itself from a short distance small pieces of paper. If now, after the sealing wax has been rubbed with the flannel, it

is passed over the box containing the radium, its power to attract the pieces of paper is lost. (2) Mammals are killed by exposing them to the radium from a distance. Mice were used, and were placed in glasses which were covered with a gauze sheet of zinc. The radium in the box above described was placed upon the cover. Such animals died within four or five days, under symptoms of paralysis of the nerve centers, while mice similarly confined, but not exposed to the radium, lived and were in healthy condition. Upon the human skin radium thus used exerts an irritating influence and produces a dermatitis. Arterial blood is darkened in color under the influence of the radium rays. (3) The blind who are slightly suscept ble to light have this susceptibility much increased when radium is brought near to the eyes The blind who have no susceptibility to light do not react to the action of radium. The blind who can detect indistinct shadows of objects upon a light background under the action of the radium are enabled to much more sharply outline the objects. In persons with sound eyes, if the same are closed and tightly bandaged, perceive the light when radium is brought within 10 to 15 cm. of their foreheads. Microscopic examinations may be made in a dark room by means of the radium rays.

*Münchener medicinische Wochenschrift, June* 9, 1903.

**Massage of the Prostate and Albuminuria.**—C. Krüger reports two cases of chronic prostatitis following gonorrhœa in which massage of the prostate gave rise to an albuminuria which was transient, but which repeated itself so long as the massage was continued. No signs of kidney trouble had previous'y been present in either case, and no casts were ever present in the urine. The cause of the albuminuria cannot be stated, but it seems certain that it was not due in any way to renal irritation, and whether it was due to the presence of prostatic excretions dislodged by the massage or to nervous or other influences is mere speculation.

**Recent Advances in the Treatment of Hay Fever.**—Arthur Thost reviews the treatment of hay fever by Dunbar's serum and confirms the latter's results. Of course, it is to be expected that this serum will only be effective in those cases in which the hay fever arises from the action of the same toxin which is used to produce the serum. Also all forms of pseudo-hay fever (bronchial asthma, influenza, and nervous disturbances are influenced by it. In complicated cases the accompanying troubles must receive appropriate medication, and even in uncomplicated cases the combined employment of the usual local applications is of benefit in cutting short the duration of the attack.

**A New Operation for Detached Retina.**—Leopold Müller gives a new operation which he has employed in seven cases with excellent results. The method consists of three steps. (1) Temporary resection of the external margin of the orbit according to Krönlein. (2) Exposure of the bulbus. (3) The excision (posteriorly) of a small portion of the sclerotid (a piece 8 to 10 mm. broad by 20 mm. long); the evacuation by puncture of the subretinal transudate through the site of the removed portions of the sclerotid; and the union by sutures of the edges of the excision so as to put this coat of the eyeball somewhat upon the stretch. While by this method it is not possible to evacuate all of the subretinal fluid, experience has shown that the portion which remains is rapidly and completely absorbed. The anterior chamber is not abnormally deepened, as might be expected by the operation.

*Deutsche medicinische Wochenschrift, Juni* 4, 1903.

**Spirit of Soap as a Disinfectant for Surgical Instruments.**—Schumburg shows Gerson's recommendation of this method of disinfection of surgical instruments is not sound. Instruments infected with staphylococci and submitted to Gerson's process are not disinfected, as may be demonstrated by making cultures from them into nutrient bouillon, when the staphylococci upon them will be found to be still alive. Gerson in testing his method used solid media for transplantation from his supposedly disinfected instruments, and because no growth took place upon such solid media, he thinks that the disinfection of his instruments was complete. It is generally conceded that for such tests as these, fluid and not solid media should be used, in order that the results obtained may be without reproach.

**Mechanism of Strangulation of the Gut.**—Josef Kertesz reviews Wilms' recent explanation (*Deutsche medicinische Wochenschrift*, 1903, No. 5) and does not entirely concord therewith. While it is true, as Wilms points out, that the increase of the intestine within the strangulation is due to the pulling in of the "efferent" arm of the gut, it is not true that such a pulling action is due to an increased peristalsis of the intestine within the strangulation, as Wilms supposed. The experimental observations of the author conclusively show that soon after strangulation the peristalsis of the involved intestine rapidly decreases and is soon practically gone. There is, hence, no such thing as increased peristalsis of strangulated intestine. It is much more probable that the pulling in of the "efferent" intestinal arm is due to the increase of fæces, gas, etc., within the strangulated intestine, and also to the increased intraabdominal pressure present.

**A Case of Head Tetanus with Peculiar Etiology.**—Albert Schültze reports a case of head tetanus which was caused by the bite of a peacock upon the forehead of the patient. The first symptoms developed four days after the injury was received, and consisted of a paralysis of the left half of the face. The tetanic symptoms first appeared on the eighth day after the bite, and were confined to the muscles of the right half of the face and those of the head and neck. Recovery took place slowly following the administration of 250 units of Behring's antitetanus serum. During the entire course of the disease there was no elevation in temperature. The diagnosis was confirmed by the isolation of tetanus bacilli from the wounded tissues and also from a small portion of the beak of the peacock which had become embedded therein. In addition to such isolation portions of these tissues were inoculated into mice and guinea-pigs, these animals dying in due time under the typical picture of tetanus.

*French and Italian Journals.*

**Physiology of the Orbital Lobe.**—From the results of his experimentation Luigi Ferrannini concludes that lesions of the orbital lobe always produce persistent hyposmia and frequently hypogeusia on the same side as the lesion; often a transitory motor deficiency of the opposite side, and very often a transitory hypoæsthesia variously situated in relation to the lesion abrasion of the cortex of the lobe constantly produces degeneration of a bundle of the connecting fibers which lead from the orbital lobe to the zone of Rolando on the same side as the lesion.—*La Riforma Medica*, June 3, 1903.

**Tremor and Hemiparesis Following Malaria.**—Guido Salmoni reports the case of acute attacks of malaria in an old malarial patient, in whom the previous history, the condition of the spleen, and the presence of the parasites were all sufficient for a positive diagnosis. The special point of interest was the presence of disturbances of the nervous system, tremors, slight contracture and paresis of the left arm, and paresis of the left leg. Other predisposing causes, such as arteriosclerosis and alcoholism, having been excluded, malaria remained as the only possible etiological factor. The author believes that this sequela to malaria has not before been reported.—*Rivista Critica di Clinica Medica*, June 6. 1903.

**Ocular Manifestations of Hereditary Syphilis.**—E. Sendral observes that hereditary syphilis frequently causes interstitial keratitis, which may disappear without leaving a trace. A return of the trouble is apt to occur, especially if a first attack have left any corneal opacity; it is always grave because it involves the deeper membranes and endangers vision. Treatment must be energetic and prolonged. Hereditary syphilis is frequently developed in subjects predisposed to lymphatic and scrofulous troubles, a fact which explains the remarkable tenacity of the affection observed in many cases. The treatment of interstitial keratitis should, as a rule, be that of syphilis. Mercury alone will give better results than mixed treatment. The iodide of potassium, which frequently has such marked action on syphilitic manifestations, is less successful in the case of ocular lesions.—*Recueil d'Ophtalmologie*, May, 1903.

**The Diagnostic Value of Leucocytosis.**—Fernand Bezancon and Marcel Labbé state that polynuclear hyperleucocytosis is the rule in acute suppuration; this fact is of value in the diagnosis of appendicitis and of pelvic suppurations. In a patient suffering from fever with a typhoid state, the demonstration of leucocytosis with polynucleosis would point to some frankly inflammatory process, and exclude typhoid or miliary tuberculosis. Malaria gives a mononuclear hypoleucocytosis. In cachectic conditions, not accompanied by fever, the presence of polynuclear hyperleucocytosis with anæmia may lead to a diagnosis of cancer. In the differential diagnosis of ganglionic tuberculosis, lympho sarcoma, and simple lymphadenitis, an examination of the blood is of the greatest value; the last-named affection alone showing a normal number of leucocytes with predominence of mononuclears.—*Gazette des Hôpitaux*, June 6, 1903.

**The Prophylaxis of Deafmutism.**—M. Lafite-Dupont would have marriages between deaf mutes and between closely related individuals forbidden, for the avoidance of congenital deaf-mutism. The affection may be acquired

rarely by malformation or arrest of development (in which case it is incurable), or, as is more usually the case, by disorders of the auditory apparatus. The latter is more apt to be involved in childhood than in adult life. (1) Because it is more delicate and vulnerable from its anatomical structure and its relation to adenoid growths and to the tonsils. (2) It is affected by the diseases of childhood, such as lymphatism, scrofula, coryza, scarlatina, measles, diphtheria, mumps, meningitis, and traumatism. (3) Discharges from the ear are frequently neglected either because of carelessness, or an ignorance which holds that suppuration is beneficial. Certainly 20 per cent. of the cases of acquired deaf-mutism could be avoided by prompt treatment, especially of aural discharges, coryza, and adenoid growths.—*Gazette Hebdomadaire des Sciences Médicales*, June 7, 1903.

**Tumors of the Kidney in the Adult and in the Child.**—Léon Imbert says that the symptoms of this affection are: (1) Hæmaturia frequent in the adult, exceptional in the child. (2) The tumor itself, noted as a first symptom in about 20 per cent. of the cases in adults, usually the first symptom in the child. (3) *Pain* is neither characteristic nor constant, except perhaps in children. (4) The urine is but slightly altered, except for albuminuria. Disorders of micturition are rare in the adult; in the child there may be retention, incontinence, or even symptoms of cystitis. (5) Compression symptoms may point to compression of the nerves, causing neuralgia and paralysis of the ureter, or of the intestines. Varicocele is apt to occur late in the disease. As to treatment, operation is, of course, the only resource. In adults the statistics of nephrectomy are: 20 per cent. of mortality after operation, 50 to 60 per cent. of a return of the neoplasm, 20 to 30 per cent. of cures. The results are not brilliant, but will doubtless be better when physicians have learned how to make an early diagnosis. In the case of children, the statistics are: 25 per cent of deaths after operation, 63 per cent. of relapses, 12 per cent of cures.—*Gazette des Hôpitaux*, May 30, 1903.

## Book Reviews.

THE PRACTICAL TREATMENT OF STAMMERING AND STUTTERING, with Suggestions for Practice and Helpful Exercises. By GEORGE ANDREW LEWIS; and a Treatise on the Cultivation of the Voice. By GEORGE B. HYNSON. Detroit: George Andrew Lewis, 1902.

We have looked over this book with considerable interest. While we are convinced that personal touch with a good teacher is the best method of curing stammering, we realize that there are many to whom this privilege is denied and for such we believe that the work will prove valuable for "home treatment." It is written in a plain style and ought to be intelligible to anyone of ordinary capabilities. On the other hand, we feel that the author has made a too-sweeping statement when he says that doctors have failed to cure stammerers. In many cases there are faulty conditions of the upper-air structures requiring correction before teaching exercises will be of any benefit whatever. Doubtless, however, the majority of stammerers are free from these anatomical defects. While the author admits that surgery may do a noble work in some cases, he does not bring out to our minds forcibly enough the cooperation that should exist between the physician and teacher. The portion of the book devoted to voice cultivation traverses only familiar ground. An excellent collection of poems designed for practice in speaking closes the volume.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS. By ROBERTS BARTHOLOW, M.A., M.D., LL.D. Professor Emeritus of Materia Medica, General Therapeutics and Hygiene, in the Jefferson Medical College of Philadelphia; formerly Professor of Materia Medica and Therapeutics and of the Practice of Medicine in the Medical College of Ohio; Fellow of the College of Physicians of Philadelphia; Member of the American Philosophical Society; Honorary Fellow of the Royal Medical Society of Edinburgh; Honorary Member of the Société Medico-pratique de Paris, and of Various National, State, and County Medical Societies. Author of a Treatise on the Practice of Medicine; of a Treatise on Medical Electricity, of a Manual of Hypodermatic Medication; of the Russel and Jewett Prize Essays, and Prize Essays of the American Medical Association and of the Rhode Island Medical Society, etc. Eleventh edition, revised and enlarged. New York and London: D. Appleton & Company, 1903.

SINCE 1876, when the first edition of this standard work was published, there have appeared eleven editions, each one brought to a higher point of efficiency than its predecessor. In the present issue that author has incorporated such new remedies as in his judgment had a claim to recognition, and has maintained the same character of the work which has made the book such a popular one.

Not only are the drugs and chemicals fully described, but diet, beverages, water, heat, air, massage, aquapuncture, bloodletting, hydrotherapy, etc., claim considerable attention from the writer. As a "storehouse of facts relating to materia medica and therapeutics," as the author describes his work, the volume before us certainly fulfils the intention of the writer; as a guide to the student or reference handbook for the practitioner it can be highly commended.

A TEXT-BOOK OF PRACTICAL MEDICINE. By WILLIAM GILMAN THOMPSON, M.D., Professor of Medicine in the Cornell University Medical College, New York City; Physician to the Presbyterian and Bellevue Hospitals, New York. Second Edition, Revised and Enlarged. New York and Philadelphia: Lea Brothers & Co., 1902.

THE first edition of this text-book was published about two and a half years ago, and already several important articles have had to be rewritten—a sufficient evidence of the rapid progress in medical science which the present generation is witnessing. Among the articles which have been so extensively revised are yellow fever, dysentery, and malaria, and many sections in the articles on diseases of the heart and of the blood have also been practically rewritten. Other minor changes have been made, part cularly in the therapeutical chapters, in several of the other articles. Dr. Thompson's work is distinguished especially by its clear directions concerning the treatmen of disease, and for this is valued above some of its riva s. We wish we could always agree with the writer, however, but he seems to us to be somewhat inclined to nihilism. The evidence of the value of salicylate of sodium and carbonate of creosote in the treatment of pneumonia, for example, is too strong, and this use is too wide spread to justify a writer in ignoring them entirely and dismissing the subject with the remark that "medicinal treatment has no positive influence upon the course of the disease." The writer does not sin in this respect very often however, and on the whole is a trustworthy guide.

THE MYCOLOGY OF THE MOUTH. A Text-book of oral Bacteria. By KENNETH WELDON GOADBY, D.P.H., Camb., L.R.C.P., M.R.C.S., L.D.S. Eng. Bacteriologist and Lecturer on Bacteriology, National Dental Hospital, Sen. Dental Surgeon Seamen's Hospitals; Hon. Lecturer on Hygiene of the North London School of Tropical Medicine; Late Demonstrator of Practical Dentistry, Guy's Hospital Dental School, London, New York and Bombay: Longmans, Green & Co. 1903.

THE specializing tendencies of the times are well illustrated in the title of this book, for not only is the science of pathogenic microorganisms divided off from bacteriology in general, but even the former has been found too wide a field and is being cut up into smaller holdings so that each can be tilled more thoroughly. As the author tells us, a large proportion of the fifteen hundred microorganisms which have been described and classified are to be found in the mouth, although, fortunately for poor suffering humanity, not all of these are pathogenic. Although the book was written primarily for dental students, it will be found of equal value to students of general medicine, and will prove a treasured addition to the library of workers in microparasitology. The mouth harbors microorganisms of all sorts and kinds—some of them of a higher station than the humble schizomycetes, for which reason Dr. Goadby has chosen the title Mycology instead of Bacteriology, as being more inclusive. In addition to the purely descpritive portions of the work, much space is given to the practical details of laboratory work, the aim of the author being to prepare a complete manual for the student whose other labors will not permit him the luxury of an elaborate course, in general bacteriology and bacteriologic technique. Dr. Goadby has done his work well and has made a commendable book.

PHOTOTHÈRAPIE ET PHOTOBIOLOGIE ROLE THÈRAPEUTIQUE ET ROLE BIOLOGIQUE DE LA LUMIERE. Par les Docteurs LEREDDE et PAUTRIER. Paris: G. Naud, Editeurs, Rue Racine, 3, 1903.

THIS work has a preface by Finsen, who gives the authors, as it were, his sanction and commendation. Half the book (134 pages) is taken up with the biological rôle of light, and most of this could have been written before phototherapy became known. The *x*-ray is scarcely mentioned (one page). The subjects of lupus and lupus erythematosus are those almost exclusively considered, about ten pages being devoted to other dermatoses. It is an interesting and well written work, of interest to those who have to do with actinic-ray treatment, but naturally covers a rather restricted field.

# Society Reports.

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*180th Regular Meeting, Held Friday, April 3, 1903.*

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

**Spasmodic Torticollis Relieved by Operation.**—Dr. ROBERT ABBE presented a woman, who came under his observation about three years ago. According to her history, she had first noticed a trembling of the head thirteen years ago. Gradually this became more severe, and was accompanied by a spasm of the neck, which drew the head around to the left side. These spasms became more violent in character, and the tremulous movements were almost constant. When she first came under his care, three years ago, the head was constantly drawn over the left shoulder and could only be straightened momentarily with considerable effort. The spasmodic movements calmed down at night and while the patient was in the recumbent position.

The first operation done by Dr. Abbe on this case was a resection of the second posterior cervical nerve, which was followed by only much improvement. A few months later, under cocaine, he divided the tendon of the sternomastoid muscle at its sternal attachment, as this seemed to be the only remaining muscle in spasm. This operation was done two and one-half years ago; it was followed by marked and immediate improvement, which had continued up to the present time. The patient was now able to keep her head in the straight position without effort and the trembling had entirely ceased.

Dr. Abbe said his idea in dividing the tendon of the sternomastoid on the right side was to put that muscle at rest; it was much hypertrophied, while the muscle on the opposite side was correspondingly atrophied. The scar from the first operation was along the hair-line, and quite insignificant. The union of the sternomastoid tendon presents no defect, and the case is one of particularly gratifying outcome.

Dr. CHARLES L. DANA said that his experience with spasmodic torticollis in recent years had led him to favor operative interference in spite of the fact that the disease was a central scortical. In one of his cases where the spinal accessory alone was divided, no improvement followed, but in two other cases where the resection included the spinal accessory and the posterior cervical the results were excellent. The speaker said that the improvement was due to the division of the nerves and also of the muscles. This subject had come up for discussion at a recent meeting of the American Neurological Association, and he then had expressed the opinion that in operating on these cases, the nearer one got to cutting off the patient's head, the better the result because it gave more rest to the muscles, and the best treatment, aside from surgical measures, was prolonged rest.

Dr. M. ALLEN STARR said he had never been able to convince himself that torticollis was a peripheral disease. The spasmodic movements of the head in these cases resulted from the combined action of certainly two muscles, and very often five or six. In Dr. Abbe's case, for example, the sternocleidomastoid of one side was concerned in the movements, and the splenii of the other, and his result was obtained by cutting off the action of two separate and distinct motor mechanisms. It stood to reason, the speaker thought, that these complex movements were of central origin and the result of cortical irritation. In the majority of cases that had come under his observation there was a history of mental shock or prolonged worry. The condition was practically analogous to a cortical epilepsy. He did not know that any one had ever attempted to operate on the brain in these cases, and exsect the cortical center for the movements of the head, but that seemed to him a more rational surgical procedure than to divide the muscles or nerves. In a number of patients whom he had had operated upon by the latter method the result had never been absolutely satisfactory. Even in the case shown by Dr. Abbe there was a noticeable twitching of the head at times.

The President, Dr. BRYANT, said his experience in this method of division was limited to a single case, in which he made quite a wide resection of the spinal accessory. It relieved the patient's symptoms for a time, but he subsequently learned that they recurred. He agreed with Dr. Dana that resection of the spinal accessory alone rarely did much good, and he favored the combination nerve operation—cutting also the muscle.

Dr. Abbe, in closing, said that in one very severe case of torticollis he had obtained some amelioration of the symptoms after resection of the posterior cervical; he then resected the spinal accessory, and the effect of the two operations was such that it almost incapacitated the patient. In another case he had operated on, the result of these operations on the nerves alone also proved unsatisfactory. His present feeling is that temporary paralysis of the muscles involved in the spasm, by section of their tendons, or transverse muscle division, is much better than resection of the spinal accessory—which is permanently disabling. Yet the resection of the posterior root of the second and third nerves is effectual and easier than muscle division extensively carried out.

**An Unusually Extensive Development of Gouty Tophi.**—By Dr. W. GILMAN THOMPSON. The patient was an Englishman, forty-three years old, a valet and butler by occupation, who for twenty years had suffered from frequent attacks of gout, which had increased in severity during the past five years. His hands and feet, and to a great extent the knees and elbows, were covered with numerous tophaceous nodules of various sizes, many of them being as large as a hen's egg. The patient's family history was negative, with the exception of the fact that his mother had suffered from rheumatism. He had never suffered to any extent from other than the arthritic symptoms of gout, and has had very little gastrointestinal disturbance. There were no evidences of kidney disease. The heart gave evidences of myocarditis, and occasionally the patient had attacks of shortness of breath and cyanosis.

Dr. Thompson said the main points of interest in the case were, first, the absence of a hereditary element; and, second, the unusual number and size of the tophi, which were, for the first part soft and motile, many of them moving with the tendons of the hands. Others were situated upon the palms and palmar surfaces of the fingers and on thumbs, yet the finger joints were fairly movable.

In connection with this case, Dr. Thompson showed a photograph of a patient who had a large number of tophaceous nodules in the scrotum. One of these masses had been excised and examined; its contents consisted of phosphate and carbonate of calcium, but no sodium biurate crystals were found. The speaker said he was aware of the fact that in the region where these masses were situated the sebaceous follicles sometimes degenerated and became calcareous, but in this case the tumors had all the nodular, non-cystic appearance of gouty deposits, although they did not contain sodium biurate. The patient showed no other tophi excepting one or two in the ear, but he gave a definite history of true Sydenham's gout.

Dr. EDWARD G. JANEWAY said these tophi were occasionally seen in patients who gave no history of acute gout nor involvement of the joints. He very recently saw a woman who had never had inflammatory symptom of gout, and still she had a number of these tophaceous nodules on the hands and underneath the skin. They had been developing during the past ten years. The speaker said he had examined the contents of many of such nodules, and had always found the sodium biurate crystals.

Dr. DANA asked whether it would be wise to resort to surgical measures in the removal of these matters? The patient stated he had had one or two removed, and the results were not very good.

Dr. ABBE said that an examination of these tophaceous nodules with the *x*-rays had shown that the bone was usually invaded by the calcareous deposits, in some instances to such an extent that there was actual displacements of the bones at the knuckle. Under such circumstances, we could not expect much from a surgical operation, as it might be necessary, in order to remove these masses, to curette away a good part of the joint itself.

Dr. THOMPSON said, that in the case he had shown the tophi seemed to be quite movable and largely superficial.

**Arterial Disease as a Cause of Nervous Affections.**—Dr. M. ALLEN STARR read this paper (p. 1).

Dr. HENRY F. WALKER referred to a not infrequent class of cases in which, at a certain period of life, attacks of persistent and severe migraine cease, and are replaced by gouty symptoms and a tendency to the development of arteriosclerosis. He was at a loss to explain this curious phenomenon, which could often be prognosticated with a fair degree of accuracy.

Dr. W. GILMAN THOMPSON said he had been greatly interested in what Dr. Starr said in regard to the influence of arteriosclerosis, with intermittent attacks of high arterial tension, upon the nervous system. In a case of this kind which recently came under his observation the speaker said he attributed the accentuation of the tension primarily to intestinal auto-intoxication resulting from long-standing constipation, and secondarily to a syphilitic history. Treatment directed along those lines proved successful in that instance. Dr. Thompson referred to another case, now under his observation, in which the following complex symptoms occurred: There was sudden hemianæsthesia, with aphasia, strabismus and dilatation of the pupil on the right side, and weakness of the extremities. There was partial loss of consciousness. This varied series of nervous phenomena disappeared completely within a day or two, or sometimes a few hours, and the patient was then as well as ever. It was hardly possible to conceive that they were due to embolism or thrombosis. The patient had had a number of these attacks, which were always similar in character, and always accompanied by a very marked increase in the arterial tension, and by marked diminution in the quantity of urine. Their disappearance was hastened by the free use of vasodilators. The speaker said he agreed with Dr. Starr regarding the unsatisfactoriness of using these remedies for any extended period, and the better results obtainable by the employment of hygienic measures. For that reason, patients who were not bed-ridden were much better subjects for treatment. Dr. Thompson said he had seen several well-marked cases of temporary hemiplegia occurring in adults, in connection with a high-tension pulse and great thickening of the arteries, which closely resembled typical examples of the type of hemiplegia caused by cerebral hemorrhage, but the symptoms lasted a few hours only, and were probably dependent upon a transient increase in the arterial tension. In conclusion, the speaker said that while the nervous symptoms to which Dr. Starr had referred might conceivably be due to a lack of thyroid extract or other internal secretion in some instances, he was convinced that they were more frequently due to intestinal auto-intoxication, and were favored by the renal insufficiency which often existed in such cases.

Dr. FRANCIS P. KINNICUTT called attention to the fact that a large proportion of the cases of neurasthenia occurred at an age antedating the usual period of arterial degeneration. While he agreed that in many of the exacerbations of the neurasthenic state there was an increased arterial tension, he thought that the explanation for this must be sought for elsewhere than in arterial degeneration. Possibly, as Dr. Starr had suggested, it was due to a perverted function of one or the other of the various glands supplying the internal secretions, rather than to actual disease of the arteries. Dr. Kinnicutt said it was a well-known fact that even advanced endarteritis, although a condition to be deplored, was consistent with prolonged life.

Dr. CHARLES STEDMAN BULL said he had been particularly interested in Dr. Starr's paper, because it was along the line of some investigations which he had been carrying on for several years. During the past winter he had seen three cases of gradually progressing ophthalmoplegia, one involving the external rectus, and the other two the various branches supplied by the third nerve. Two of these patients were over fifty years of age; the third was a young woman of about twenty, who had been under his observation for the past seven years. In her case there was advanced arterial sclerosis of the retinal arteries, as well as of the temporal and radial. In these cases, anti-syphilitic treatment produced no appreciable benefit. Another condition directly connected with the remote effect of arterial disease was observed in those cases which had long been classed as simple chronic glaucoma, but which were now to be regarded as the result of progressive atrophy of the optic nerve, and which were probably produced by pressure upon that nerve either within the optic canal or back of it by the sclerosed ascending internal carotid or by the rigid ophthalmic artery or by both.

Dr. BULL said he recently saw a marked example of the type of undeveloped children which Dr. James had referred to as being quite common in the better walks of life. The patient he had in mind was a girl of seventeen, who had the appearance of a child of twelve or thirteen: she was undeveloped both mentally and physically, and had never been able to get any education. An examination of her eyes showed no errors of refraction nor muscular defect, but furnished one of the most marked examples of retinal arterial sclerosis he had ever seen at any age.

Dr. CHARLES L. DANA said there were a number of nervous diseases and conditions which were recognized as being connected with arteriosclerosis. During the past winter the speaker said, he saw three patients who were, apparently, suffering from brain tumor. One of the patients had Jacksonian epilepsy, headaches, vomiting and such distinct evidence of a brain tumor that an exploratory operation was done. The only lesion discovered was a patch of softening due to obliterating endarteritis. In two other cases which simulated brain tumor, with headaches, Jacksonian epilepsy and slight paresis of one arm, the clinical directory later pointed to an oblitering endarteritis. Dr. Dana said that in old people, very persistent, severe and diffuse headaches sometimes developed, associated with marked evidences of arterial sclerosis. Occasionally, these headaches will terminate in some crisis, such as a convulsion or an attack of hemiplegia. The speaker said he could not quite agree with Dr. Starr in regard to the influence of the arterial system upon spinal cord diseases: for example, in myelitis, whether syphilitic or otherwise, the vascular condition was usually secondary; the same was true of the combined sclerosis. Some years ago, Dr. Dana said, he reported a case with autopsy of senile paraplegia which was due to an obliterating endarteritis. He was quite convinced that many peripheral nervous conditions were dependent upon interference with the vascular supply: this included most of the cases of neuralgia in elderly people. Half a century ago, Dr. Austie made the statement that migraine usually ceased after the age of forty-five or fifty, but was sometimes followed by some other form of neuralgia. Another condition, due to vascular trouble, was that known as "intermittent claudication," which followed the sudden obliteration of the artery of the leg. Erythromelalgia and Raynaud's disease have also been attributed to obliterating endarteritis. He did not regard arteriosclerosis as the sole or most important factor of neurasthenia, but it certainly had some bearing upon cer-

tain cases. He thought that neurasthenia often had a bad myocardium and cardiac tonics were usually more beneficial than arterial dilators. His attention had recently been called to thyroid extract, in doses of from one-sixteenth to one-tenth of a grain, as an excellent cardiac stimulant. He had found pilocarpine, in doses of from one-tenth to one-fourth of a grain, accompanied by a a glass of hot water, a good remedy for alleviating some forms of arteriosclerosis.

Dr. EDWARD G. JANEWAY said he had seen a good deal to confirm what Dr. Starr had said in regard to the effect of arterial changes upon different diseases of the brain and cord and nerveous system generally. In treating arteriosclerosis, the speaker said he relied very much upon potassium iodide, in doses of five to ten grains; he thought this remedy was far better than nitro-glycerin for continuous use. The nitrate of sodium had recently been pronounced dangerous for continued use, it being claimed that it was apt to produce severe gastric symptoms. In connection with arteriosclerosis, the condition of the heart should always be carefully considered in estimating the gravity of the condition.

Dr. HERMANN M. BIGGS said it had always seemed to him that patients with arteriosclerosis did best and lived longest in those instances where the disease was pretty extensive in the medium sized and large arteries, and where the arterial walls yielded rather early to the tension, resulting in considerable dilatation, so that the supply of blood was maintained fairly well. In the other class of cases, where the medium sized vessels were not so seriously affected, but were thickened and the calibre reduced and the tension was maintained, we were more apt to find more serious impairment of the supply of blood through the small vessels. The speaker said he recently seen a case of arteriosclerosis following alcoholism and syphilis, in which the effects of large doses of nitroglycerin were strikingly shown. The patient was a man about forty-eighty ears old, with gangrene of the left foot. There was no pulsation in either femoral nor in the left brachial, while that in the right brachial was very feeble. The man was in a stuperous condition; he had considerable temperature, his heart action was very feeble, and it seemed as though he would die within a few hours. Under enormous doses of nitroglycerin, however, his condition improved wonderfully. The circulation was fairly well restored in the right leg, and the coldness and blueness of the limb, which had progressed as far as the knee disappeared. He improved to such a degree that he was able to be up and about the wards, but six or eight weeks later he developed a cerebral hemorrhage and died. Dr. Biggs said it had always seemed to him that in cases of neurasthenia associated with arteriosclerosis, the cause which was back of the arteriosclerosis was also back of the neurasthenia; that both were the result of the same form of poisoning.

Dr. BEVERLEY ROBINSON said that while in many cases of arterial tension, nitroglycerin or amyl nitrite gave good results, there were other cases in which the effects of these and similar drugs were quite unsatisfactory or even entirely wanting. His experience had led him to believe that in certain cases of arterial tension and changes in the arteries the conditions could best be treated, not by drugs, but by more rational measures, such as better hygienic surroundings, careful dieting, etc. Five years ago, the speaker said, he visited several of the larger hospitals in Paris, and he found that there the view was generally held that the nitrites should not be employed to relieve arterial tension unless some very manifest symptoms were present. The possibility of an associated renal lesion in these cases should not be overlooked. An atrophic kidney or interstitial nephritis may at times be easily recognized, and again the presence of such a condition may be readily overlooked. While in such a case the kidney itself did not change, its functionating power did, and in consequence of this the urinary symptoms varied widely at times. Dr. Robinson said he felt confident that there were cases where certain nervous symptoms which were attributed to arterial changes were not really dependent upon the latter, and failed to improve after the arterial conditions had been modified.

Dr. W. GILMAN THOMPSON said it was exceedingly important to distinguish between arterial tension and arteriosclerosis. We should remember that the latter was often quite localized, perhaps in the brain or peripheral vessels, or elsewhere. There was probably no better field for observing arteriosclerosis than Bellevue Hospital, where so many of the patients had a syphilitic and alcoholic history, and were workingmen whose circulatory system had long been subjected to great strain. It was the exception rather than the rule there to find a man of forty with normal arteries. In the majority of patients of that class at that age, arteriosclerosis was fairly well developed, and yet those patients did not suffer often from purely functional nervous disorders. The more extensive the thickening of the vessels, the less likely was the patient to develop temporary functional nervous disorders. Dr. Thompson said that postmortem examinations had shown that we were very apt to be misled by the sense of touch as to the extent to which arterial sclerosis had progressed in a given case. The speaker was inclined to believe that the functional nervous phenomena under discussion depended more upon vasomotor neurosis affecting a large number of vessels and modifying their function, than upon structural changes in the vessel wall.

Dr. Kinnicutt referred to the recent pathological findings in three cases of erythromelalgia reported by Shaw, of the University College Hospital, London. In all, vascular changes were present. The changes consisted of an increase in the intima of the arteries of the affected parts, and occasionally in thrombosis and changes in the inner coat of the veins. The nerves, even to their terminations, showed no indication of degeneration, and there was no increase of fibrous tissue in the trunk of the nerves.

Dr. STARR, in closing, said that in a paper of the character he had presented, which only dealt with a certain group of cases depending on arteriosclerosis, one was liable to be accused of striving to cover too much ground. He realized that there were many cases of neurasthenia that were not traceable to arterial changes. Migraine was due, ninety-nine times out of one hundred, to some toxæmic condition, a fact which had been worked out by Rachford of Cincinnati. Occasional cases, however, were associated with arterial sclerosis. While neurasthenia was usually dependent upon toxic states, nevertheless it was not at all unusual to observe it in men of middle life who were laboring under great pressure and carrying heavy responsibilities, and in those cases it was not attributable to toxæmia, but to arterial changes which in the course of time, perhaps, eventuated in an attack of apoplexy. Dr. Starr said he thoroughly agreed with what Dr. Dana had said regarding the possibility of arterial sclerosis giving rise to symptoms which it was difficult to distinguish from those of brain tumor. As an example of this, he reported the following case: The patient was an elderly man who was apparently suffering from a tumor of the brain, and Dr. Starr was asked to see him in consultation and help decide whether the case was an operable one or not. The symptoms were choked disk, intense headache, an occasional convulsion, hemiplegia and hemianopsia. On account of the diversity of the symptoms it was decided not to operate, and the conclusion was reached that if they were due to tumor, the lesions must be multiple. The patient died and at the autopsy no tumor was found, but the cerebral blood vessels were sclerosed to such a degree that they looked likes pipes of lead. The entire brain was riddled with areas of softening. The arterial sclerosis was apparently limited to the brain, and the arteries at the temple, wrist and feet were quite soft.

Dr. Starr showed a photograph of a case of hemiatrophy of the face that had made rapid progress in two years

## NEW YORK STATE MEDICAL ASSOCIATION.

FIFTH DISTRICT BRANCH.

*Nineteenth Annual Meeting, Held in New York City, May 19, 1903.*

PARKER SYMS, M.D., PRESIDENT.

**Symposium on Malaria: Morphology of the Anopheles Mosquito; Its Habits; Modes of Destruction.**—Dr. W. N. BERKELEY opened the discussion with a paper having this title. Three species of the anopheles were described, and attention was called to the fact that there were many enemies of the larvæ. He said there was no permanent remedy against anopheles except drainage, but there were several well-known methods of temporarily ridding a neighborhood of these pests.

**Laboratory Diagnosis and Life Cycle of the Parasite of Malaria.**—DR. W. T. KLEIN read this paper. He said that as the malarial plasmodium could not leave the body of itself, and was not found in the stools. it was natural to look for an agent of such transmission. This was found in the mosquito. Further study brought out the now well-known fact, that there were two cycles, viz.: (1) The endogenous cycle in the body of the human, and (2) the exogenous cycle in the body of the mosquito. The tertian organism being the commonest in this latitude, was taken for study. The parasite was seldom, if ever, found free in the plasma. Just after the chill it could be seen in the red cells as an unpigmented. spheroidal body which, in the unstained and fresh state, was actively amœboid. In the next stage there was formed, usually within two hours after the chill, the characteristic ring. This gradually increased in size, and showed active amœboid movements in the unstained specimen. As the ring increased in size a thickening of the protoplasm developed at one section, and the body assumed a more nearly spherical form, while the pigment granules became more numerous and the chromatin broke up. At the end of the first twenty-four hours the organism occupied about three-quarters of the invaded red cell. In the full-grown organism the nucleus broke up into a recticulum, which invaded the protoplasm and the chromatin granules continued to divide, becoming fewer in number and larger. The breaking up of the segmenting body and the liberation of the spores were synchronous with the rigor. The cycle was completed approximately in forty-eight hours. Almost from the very beginning the erythrocyte became swollen and soon exhibited a granular degeneration of its protoplasm, which was best demonstrated by the staining method of Goldhorn. The quartan ring resembled that of the tertian, but was slightly smaller and its pigment granules were smaller and more numerous. There were usually between six and twelve spores, and the cycle was completed in seventy-two hours. The rings of the æstivo-autumnal form were distinctly smaller than those of the tertian, and the rings were more delicate and symmetrical. The full-grown and segmenting forms were seldom seen in the peripheral circulation. Two distinct types of æstivo-autumnal forms were recognized, one having a cycle of twenty-four hours, and the other having a cycle of forty-eight hours. The crescent body was an intracellular body of crescentic shape with the horns somewhat rounded. The full-grown body contained one or two centrally located chromatin groups surrounded by motionless pigment granules. The parasite was transferred to man by the bite of the mosquito, the disease usually developing in from eight to ten days after inoculation. All inoculations, however, were not successful, showing that certain conditions were necessary for the successful development of the endogenous cycle.

**Diagnosis.**—The blood suspected of containing the malarial parasite might be examined either dry or fresh, and the specimen should be taken, if possible, about eight hours after the chill. This was because there was a tendency for the organisms to retire to the internal organs just before the chill. Ewing claimed that in an acute malarial fever, even though quinine had been administered, malarial parasites could always be found if the blood were carefully and patiently examined within eighteen hours of the chill. It was exceedingly important that the cover glass and slide used for the examination should be absolutely free from dirt, otherwise annoying errors were apt to arise. For this microscopical examination a one-twelfth-inch oil immersion lens was required. The polychrome methylene-blue stain colored the chromatin a bright red, which contrasted well with the light blue of the intracellular organism. Certain precautions must be observed in order to obtain reliable results. The speaker said that his personal experience as examiner of such blood for the New York Health Department had led him to prefer L. B. Goldhorn's staining method to all others. The entire fixing and staining process could usually be completed in one minute, and the results were eminently satisfactory. The chief feature of this method was the beautiful staining of the chromatin granules, thus greatly facilitating the diagnosis. The errors in diagnosis were usually made with the hyaline and unpigmented forms; hence the value of a stain which brought out well the chromatin granules. A marked diminution in the number of the red corpuscles was a constant occurrence, and the cells were extremely deficient in hæmoglobin. The absence of leucocytosis was also characteristic. A rapidly rising temperature without a marked increase of leucocytosis should lead one to suspect malarial infection; on the other hand, a marked leucocytosis should make one doubt the existence of an uncomplicated malarial infection. Pigmented leucocytes should always be looked for. In æstivo-autumnal fever the parasites were always most numerous during the apyrexial stage, but there were mild forms of the disease in which the parasites could only be found with difficulty In such cases, however, pigmented leucocytes were always present.

**The Concurrence of Anopheles Mosquitos and Malaria.**—Mr. HENRY CLAY WEEKS, Engineer in Economics, presented this paper. He said that the misfortune of being ten years ahead of one's time was that one was put down as a crank, but in this instance the crank effected a revolution of ideas and was able to prove the possibility of exterminating mosquitos from a given region. He commended the quite exceptional and very progressive public spirit of the Board of Trade of Worcester, Mass., which had published an exhaustive report with regard to the existence of malaria in that place, and announced the intention of excluding it. He believed there was much yet to be learned about the mosquito, and it was sincerely to be hoped that people in many other places would not shrink from publishing the fact of the existence of malaria, and so take the first important step toward the banishment of this public disgrace. The speaker then read from various reports with regard to localities, which he was not at liberty to name, all tending to show the concurrence of malaria, with anopheles mosquitos. Attention was called to the fact that the larvæ of the anopheles were found much later in the season than those of the ordinary culex mosquito. He was now engaged in a systematic investigation with regard to malaria in the southern part of Brooklyn. He was glad to say that this movement against malaria was spreading, and he believed that in the near future the results would be remarkable and far reaching.

**Clinical Diagnosis and Treatment of Malaria.**—Dr. ALEXANDER LAMBERT discussed this part of the subject. He said that at the beginning of his medical career he had been impressed with the fact that various serious diseases, such as tuberculosis, puerperal infection, typhoid and other forms of sepsis, were very commonly diagnosticated as "malaria." This was largely because the work of Laveran was only just beginning to be appreciated, whereas now the examinations of the blood were a part

of the routine work of the hospital. We must realize that ordinarily from ten to twelve hours were required for the malarial paroxysm to pass through its complete cycle, whereas most other chills did not take so long. He had seen chills following sepsis from double ear disease which did take as long, and which, consequently, left the diagnosis in doubt until the blood examination had been made. Although there were types of malarial chills which only lasted from four to six hours, these were mild cases, and the temperature did not rise to 104° or 105° F., as in the ordinary malarial paroxysm. When the fever was 104° or over the pulse did not show a corresponding increase in frequency, being often below 100. This was not true of any other similar elevation of temperature with which he was acquainted. These observations were intended to apply only to the form of malaria commonly seen in this climate. Captain Delaney of Calcutta had recently published some interesting observations on that most puzzling form of malaria, the æstivo-autumnal type. He found that this type occurred in about 17 per cent. of the cases there on the first or a single examination, but that if the differential count of the leucocytes were made, in over 90 per cent. of the cases a justifiable diagnosis of malaria was possible. The polynuclear leucocytes were found to be undiminished, the small lymphocytes were increased, often as high as 60 per cent., and the large mononuclear leucocytes were also greatly increased. By these cells he meant all those mononuclear cells which were as large as the polynuclear ones. If they constituted over 12 per cent., he made a diagnosis of malaria. This position was supported by the reports of many cases. Only four cases appeared to be exceptions to this rule, and each one of these occurred in persons who had just developed malaria for the first time. In his cases there was usually a good proportion of hæmoglobin, and the color index was always over one. He found a very high leucocytosis only in those exceedingly severe cases of the æstivo-autumnal variety in which the parasites were present in the circulation in large numbers. With regard to the differential diagnosis of malaria from tuberculosis, the speaker called attention to the different length of the cycle, and the fact that the temperature quickly fell to normal, whereas in the early stages of tuberculosis the temperature ran from the subnormal to the subfebrile, the temperature ranging from 97° to 100° F. In sepsis the chill, the rise of temperature and the sweating occupied a comparatively small period, and recurred irregularly. In cholelithiasis there was frequently a form of fever that had been designated "remittent." When the gall-stone became impacted in the duct it was apt to cause such a fever, and this was usually associated with jaundice. Gradually the duct became dilated and the symptoms subsided, only to be followed by another impaction and other slow dilatation. This explained the remissions observed in such cases. In yellow fever, with a stationary or rising temperature there was a falling pulse; in malaria, the pulse did not continuously fall. It was often difficult to distinguish between æstivo-autumnal malaria and typhoid fever because one must accept the existence of double infections. A fever which rose in a step-like curve and did not rise suddenly and fall as suddenly, and which occurred in a case giving the history of malaise and the prodromal symptoms of typhoid, should be diagnosticated as typhoid, and not as malaria. Moreover in typhoid there would be the abdominal symptoms without much nausea or vomiting, whereas in malaria nausea and vomiting were common, and abdominal symptoms were rare. The enlargement of the spleen in typhoid did not occur as early as in malaria. The diazo-reaction in the urine was not so common in malaria as in typhoid, and the Widal reaction might be present to assist in the diagnosis. Unless the malarial parasites could be found in the blood after repeated examination, or unless the blood changes already described were not present, one should exclude malaria. In this latitude we should deal with fevers as other than malaria unless we could prove them to be malarial. This would prevent many mistakes which had occurred in the past.

**Treatment.**—Fortunately we had a specific for the treatment of malaria. The maximum quantity of quinine was found in the blood six hours after its ingestion into the stomach. The malarial parasite could only be acted upon before it had become mature. The chill occurred about the height of segmentation; hence he gave five grains of quinine every four hours, and continued it until the desired effect was obtained. After this he gave three grains three times a day for a week. In cases of severe malarial infection coming from the Philippines he had followed Manson's treatment, and had not yet seen a case in which it had not proved successful if the patient lived long enough for the quinine to be absorbed. According to Manson, five grains of quinine should be given every four hours until a decided effect was obtained and the temperature reached normal; then, three grains were given three times a day. After the temperature remained at the normal the patient was told to cut a lemon into small pieces, pulp, skin and seeds, place it in one quart of cold water and boil it down to one pint. It was then strained through muslin after having been sweetened to suit the taste. This quantity should be drank every day for four or five months. After three weeks the patient should take a calomel purge, and then three grains of quinine three times a day for one week. At the end of a month he should repeat the calomel purge and the quinine for another week, and this should be repeated at intervals of a month for four or five months, all the while drinking the lemon-juice. It was well to remember that whereas the ordinary sulphate of quinine was almost insoluble and contained only 72 per cent. of the alkaloid, the hydrochlorate of quinine was exceedingly soluble, and contained 81 per cent. of the alkaloid.

Dr. Francis P. Kinnicutt said that a knowledge of the latent phase of the plasmodium was necessary for the intelligent treatment of malaria. Ross, than whom there was no higher authority, recommended first a saline purge, and then ten grains of quinine every two hours for the first fortnight, fifteen grains daily for the second fortnight, ten grains for the second month, five grains for the third month, with ten grains instead of five grains at first twice a week, and then once a week. This dosage was intended for a person weighing one hundred and fifty pounds, and should be greater or less in accordance with variations from this standard weight. In every case of infection with the malarial plasmodium quinine should be given regularly for four months, whether relapse occurred or not. This was a most important fact to be borne in mind. He did not think that clinical experience showed that Manson's treatment was as effective in destroying the parasite as the one given by Ross. The best method of administering quinine was in acid solution; the next best was in the form of powder shaken up in water. Dr. Lambert had very properly called attention to the great solubility and strength of the hydrochlorate and the bihydrochlorate of quinine. During the continuation of the fever little benefit could be expected from arsenic, and while methylene blue appeared to destroy the malarial parasites, it did so more slowly than quinine and often gave rise to certain unpleasant effects. As a preventive of infection, when necessarily exposed to it, he advised taking five grains of quinine daily, with ten grains twice a week.

Dr. David P. Austin said that the period of incubation was about one week, and there was a strong tendency for relapses to occur at intervals of a week up to the fourth week. After this period it was not likely to recur again the same season. As an initial dose he endeavored to give, some hours before the chill, fifteen grains of quinine, ten grains of calomel and five grains of capsicum. This was usually sufficient to interrupt the chill, so that the

next one might be looked for one week later, and should be forestalled by the administration of ten grains of quinine.

Dr. W. I. Cocke of Port Washington, Long Island, spoke of some successful and permanent cures that he had obtained in a considerable number of cases from the administration of nuclein. The "Cuban Mixture," composed of sulphur, camphor and capsicum, had also proved useful in his hands.

## New Instruments.

### OBSERVATIONS ON RETRACTION AND RETRACTORS IN ABDOMINAL SURGERY, WITH DEMONSTRATION OF AN AUTOMATIC CŒLIOTOMY RETRACTOR.*

By ARTHUR STURMDORF, M.D.,
NEW YORK.

Accessibility of the surgical objective point to sight and touch dominates all operative prognosis.

In intraabdominal operations, such accessibility to sight and touch is obtained by distending the abdominal incision by means of retractors; by postural manipulations, and by partial or complete evisceration. The first of these aids, namely, retraction, is invariably essential and indispensable; while postural manipulation and partial or complete evisceration may be called into play as complementary aids.

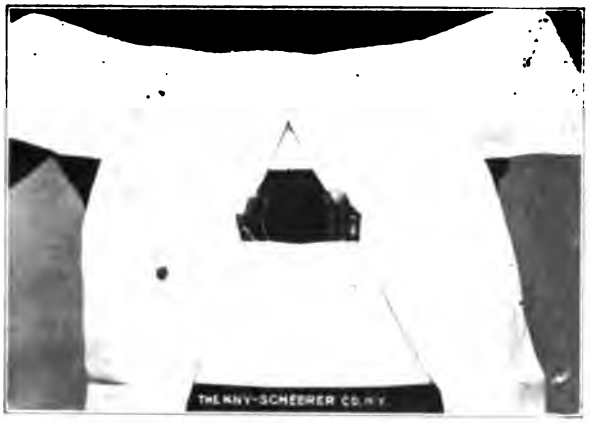
In uncomplicated abdominal conditions, with freedom from extensive adhesions, and in which the necessary operative procedures are of comparatively short duration, the enumerated means, as ordinarily employed, accomplish all that is essential. But it is otherwise in an abdomen presenting extensive and complicated agglutinations. Here we are dependent for accessibility solely upon the retractor, until by intraabdominal manipulations, sufficient visceral mobility is obtained so that postural and eviscerating aids may be utilized.

It is in *these cases of necessarily prolonged retraction* that the technical shortcomings of retractors in use at the present day become manifest.

Yet, while the *immediate detriments* from structural faults in retractors, during operation, have been fully recognized, as evidenced by the enormous variety of such instruments in vogue, there is one ultimate detriment of paramount importance, which to the present writing has received no emphasis. This ultimate detriment which distinguishes abdominal wound retraction from wound retraction in other regions, is the production of wound conditions inimical to firm union, thus favoring the development of *visceral protrusions*. The occurrence of post-operative hernia, while materially reduced in frequency by modern methods, is not entirely obviated by the same.

The most accurate layer-coaptation in suturing cœliotomy wounds cannot secure an adequate union of wound edges, bruised and devitalized by long-continued pressure and friction. I am convinced that this traumatic element also stands in causative relation to the cases of "*late gaping*" in cœliotomy wounds, which were reported recently by Collins, Lilienthal, Morris, Brewer, Moschowitz, Blake, Walker, and Foote. In discussing these cases, Dr. Erdman, reported one in which the wound opened on the ninth day, without apparent cause, and this, despite the fact that he had taken special pains in coaptating the parts at the time of operation. It is not necessary to demonstrate gross lesions in evidence. The baneful effects of antiseptics upon the healing process in clean wounds is fully recognized.

Can continuous pressure by badly fitting, pronged, toothed, or fenestrated irons be less deleterious? Pressure and bruising devitalize wound surfaces and deprive them of the two functions essential for their primary and permanent union. The cytogenetic, necessary for the production of young, healthy connective tissue cells—and the bacteriolytic, essential for the annihilation of such bacterial presence, as the



Unencumbered operative field. Note absence of projections.

Oblique retraction.

Proper method of separating blades within the wound.

Posterior view of retractor.

most scrupulous antiseptic endeavors cannot obviate.

The attenuation of a post-operative hernial covering is *not* due primarily to a simple diastasis of the parietal strata, but to a more or less extensive atrophy of the involved layers. Note the uniform absence of adipose tissue in such an incompetent scar, and the fact that, most frequently, the visceral protrusions are more prominent in the *immediate vicinity* of and *not through* the scar itself. Note the influence on the occurrence of post-operative hernia, from the pressure of drainage tube and gauze strip.

Wound retraction *is* nevertheless indispensable and its detriments must be obviated or at least mitigated. A longitudinal abdominal incision, distended laterally, presents an opening more or less elliptical in shape. The points of greatest distensibility in this elastic ellipse are in the center of its lateral borders—in other words, through its widest diameter. This distensibility diminishes rapidly from these points toward the apices of the wound.

It follows that, to obtain a maximum of distension with a minimum of force, the blades of the retractor should be so shaped as to exert the greatest traction on these points of greatest distensibility; namely, in the center of the lateral borders of the incision and neither above nor below these points.

Thus the disadvantage of the ordinary flat-bladed retractors becomes evident. The flat retracting surface being applied to the concave border of the distended incision, maximum traction is exerted by the lateral edges of the flat blade at points above and below the center of greatest distensibility; the wound becomes angulated, to the detriment of tissue and space. If we recall the direction of the vascular channels in the abdominal wall, such forcible angulation might throw some light on the etiology of thrombosis in the veins of the lower extremities, after cœliotomies running an otherwise uneventful course, as reported by Lennander, Coe, Meyer, and others.

The wider the retracting blade, the more prominently will this factor come into play. It follows that, to obtain the maximum of retraction with a minimum of injury, the shape of the retracting blade must conform to the lines of the *distended wound* and not to those of the *relaxed incision*.

Modelled on these lines, two semi-elliptical blades result, which, placed *in situ*, present a dilatable metallic ellipse fitting smoothly and snugly within the wound ellipse, thus obviating the injurious results of improper blade contour. . . . In addition to the disadvantages of improper shape the ordinary hand retractors necessitate the presence of additional assistance; an undesirable feature because additional assistance cannot always be had, and when had

entails additional sources of infection, with encumbrance of the operative field.

The instrument which I take the liberty to submit, possesses proper blade conformation and an automatic self-retaining mechanism, which enables the operator, unaided, to control any desirable amount of steady traction, in any diameter of the wound, for any length of time.

I claim but a small share of originality in the construction of this retractor. The blades are modified from Fritche's instrument, and the self-retaining mechanism was suggested by Kelly. Yet a glance will show very essential differences from both.

The instrument, as submitted, was used in a number of tedious and difficult abdominal operations, and proved itself eminently satisfactory. It enables me to carry through successfully, without any assistance whatsoever, in the presence of several of our members, a complicated gynecological extirpation, with the usual peritoneal plastic work. The instrument is simple in construction, easily disarticulated for sterilizing purposes, and free from inaccessible crevices and joints.

In applying it, it is only necessary to avoid insinuating the free edge of the blades into the preperitoneal space, preventing injury to or peeling of the peritoneum. It does not encumber the field of operation by projections of any kind. The blades rotate freely, thus enabling the operator to change the lines of traction from the transverse to the oblique or longitudinal diameter without extracting the instrument, by simply rotating it within the incision, as shown in the illustration. Owing to the shape of the blades they cannot slip either in or out of the wound. If found desirable, one blade can be easily detached during operation and the instrument used as an ordinary single-hand retractor.

It is supplied with several sizes of interchangeable blades, thus making it applicable to any length of incision. It is manufactured by the Kny-Scheerer Co. of New York.

206 East Sixty-second Street.

## THE IGNITION VACUUM BOTTLE.

### A CHEAP, CONVENIENT, POWERFUL ASPIRATOR.

By KARL CONNELL, M.D.,
NEW YORK.
HOUSE PHYSICIAN, NEW YORK HOSPITAL.

A strong clear glass bottle of medium or wide mouth is selected. For aspirating the chest an ordinary five-pint bottle of about one-inch mouth is a convenient size. This is fitted with a perforated stopper, rubber preferably, to which is attached a foot or two of firm rubber tubing clamped by a hæmostatic forceps or other device. Three drachms of 95-per-cent. alcohol is poured into the bottle, which is then turned until the entire inner surface is coated. The excess of alcohol is poured off. The bottle is then placed upright and ignited at the mouth before the film of alcohol has time to dry or settle. (Figure 1.) A sheet of flame descends into the bottle, varying in time for complete ignition from a fraction of a second to several seconds, depending on the strength of the alcohol and the temperature of the glass. As the flame touches the bottom, the bottle is quickly corked. On attaching the needle the aspirator is complete.

By this simple procedure, taking less than half a minute, one displaces regularly 75 to 85 per cent. of the air in the bottle, thereby securing an initial suction power sufficient to raise a 28-foot column of water.

The capacity is limited only by the size of the bottle. That described will aspirate 60 to 68 ounces, which in a personal experience of some two hundred tappings has been found to be the maximum amount to be removed at one time with safety and comfort to the patient. Should further aspiration be desired after this amount is reached, the cork can be loosened, the tubing led over the side of the bed and further fluid obtained by syphonage, or the bottle can be disconnected, emptied, and the vacuum reëstablished.

The suction transmitted to the needle is limited by

Fig. I.

the collapsing index of the connecting tubing. If only gentle suction is desired a few inches of soft tubing can be interposed at any point. To transmit the full suction power fairly firm tubing is necessary. The rate of flow is governed by the size of the needle, or by clamping the tubing.

Some experience is desirable to time the corking

Fig. II.

of the bottle correctly. This influences the degree of vacuum more than the rate of combustion. The temperature of the bottle should be between 60° and

110° F. At 60°, with 95-per-cent. alcohol, ignition is slow, but becomes more rapid if the temperature of the bottle is raised, until at 110° it takes place as a hoarse cough, necessitating quick corking. Below 60° the alcohol will not ignite. Above 110° it ignites so rapidly as to introduce possibly, with a weak bottle or narrow neck, an element of danger. With 50-per-cent. alcohol, or whiskey, the temperature of the bottle must be at least 85°F. for combustion to take place. Ether and other volatile substances should be avoided. The bottle in the illustration has been used over a thousand times. No accidents have ever happened.

If the vacuum should be lost through clumsy corking or leaky connections the vitiated air must be displaced by water before ignition is again attempted.

The great economy of time and labor has resulted in this device supplanting since its origin eight months ago all the expensive and rapidly deteriorating Dieulafoy, Potain, and other mechanical aspirators, and the less powerful syphon methods hitherto employed at the New York Hospital. The method has recently been introduced into Roosevelt Hospital, with satisfaction, by Dr. Geo. L. Peabody, and demonstrated by Dr. Henry P. Loomis before the Clinical Society.

The monetary feature commends the instrument to the average practitioner. It can be obtained, exclusive of clamp, at any village drug store, for less than fifty cents.

The instrument is satisfactory as an aspirator for exploring or evacuating liver abscess or empyema, or for suprapubic aspiration of the bladder. A larger bottle would provide ample suction for rapidly drying the pelvis or aspirating a cyst at the operative field. When relief from massive œdema of the legs or scrotum is sought by direct puncture, this vacuum bottle is useful to secure more rapid drainage without liability of infection. For such a purpose, a medium-sized needle is inserted deeply into the œdematous tissue, and attached to the bottle which rests clear of the bed. Twenty ounces of serum can be obtained from a single puncture of an œdematous scrotum in several hours, with relief of symptoms, in a cleanly manner, and without subsequent oozing.

---

**Gersuny's Operation for Saddle-back Nose.**—Joseph Rilus Eastman reports a case successfully treated by paraffin injections. Two cubic centimeters of molten paraffin were injected into the skin over the site of the bridge of the nose. Directions are given for the preparation of the paraffin and the method of conducting the operation. There is nothing of interest, the author says, in connection with the history of the case cited since the operation, except that the patient has suffered three or four attacks of pronounced syncope. The patient was not seen by him during any one of these attacks, therefore he has no knowledge of their character, but he suspects slight embolism. —*The Medical and Surgical Monitor.*

**Microbes at the Pole.**—Dr. J. Charcot is heading a very unusual expedition to the polar regions. On May 15 he sailed from St. Malo, France, under the auspices of the Pasteur Institute and the Museum of Natural History of Paris, to study bacteriology in the polar regions. A number of prominent investigators deny the existence of microbe life in the polar regions, and Dr. Charcot, by making repeated analyses of air and water in these regions, as well as by careful examining the intestinal tracts of polar animals for the primary microbes which are found so abundantly in warm or temperate latitudes, will undoubtedly make many interesting discoveries and definitely settle the dispute.—*Albany Medical Annals.*

### SOME RECENT METHODS OF INTESTINAL ANASTOMOSIS.*

BY GEORGE GRAY WARD, JR., M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF DISEASES OF WOMEN, AND GYNECOLOGIST TO THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; INSTRUCTOR IN OBSTETRICS AND GYNECOLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE; ASSISTANT GYNECOLOGIST TO ST. FRANCIS' HOSPITAL; FELLOW OF THE NEW YORK OBSTETRICAL SOCIETY AND ACADEMY OF MEDICINE.

INTESTINAL surgery is a subject which should be of interest to all who make any pretense to surgical work. The general surgeon must, of course, be qualified to deal with any of the complications necessitating operations upon the intestines whenever he invades the abdominal cavity. Likewise the gynecologist, equally with the general surgeon, would be incompetent to attempt any abdominal section for pelvic disease were he not thoroughly conversant with the methods and technique of this branch of surgery. The gynecologist, more frequently than not, expects to find intestinal complications in the way of adhesions when he opens the abdominal cavity; in fact, I think we may state that he has to deal with dense intestinal adhesions more frequently in his allotted field than does the general surgeon in his work in other parts of the abdomen. The obstetrician occasionally must open the abdomen, and

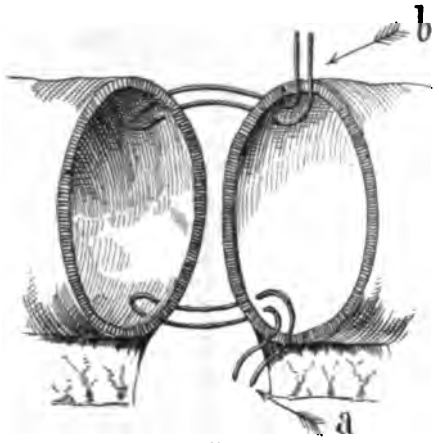

Fig. 1.

even an ophthalmologist may be called upon in an emergency to do likewise, as was the case with one of the members of this club. Suffice it to say, that the recent advances and the present status of this interesting subject, and a practical knowledge of the technique of the different methods, should be familiar to all who do abdominal work. Those who are not especially interested in this subject, may be under the impression that the problem of uniting the severed ends of the intestine has been solved of late years by the Murphy button, which is so generally used. The fact that new ideas and methods are being constantly presented in great variety goes to prove that the end is not yet and that we are still searching for an ideal.

*Read before the Hospital Graduates' Club.

Only a few years ago Senn wrote: "We have reason to believe that the technique of intestinal surgery remains an unfinished chapter, and that the ideal method of uniting intestinal wounds has not yet been devised." This statement holds true to-day, but since that time great progress has undoubtedly been made.

The history of intestinal surgery dates from ancient times, but two landmarks stand forth, from each of which great advances in the problem were made. Lembert in 1826 proved that the healing of

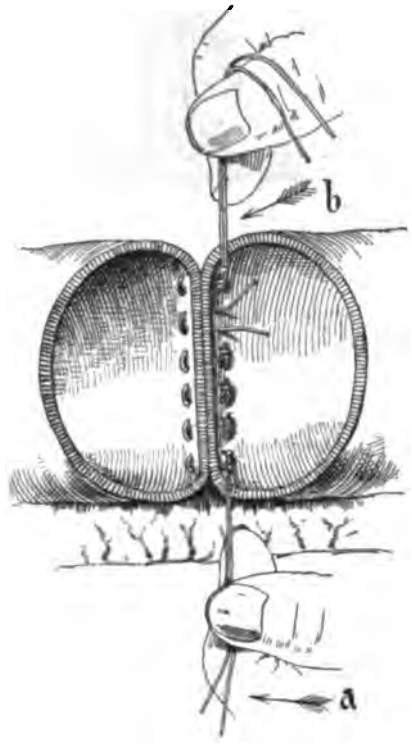

Fig. 2.

intestinal wounds takes place most constantly and speedily if serous surfaces are brought into contact, and the law of "serosa to serosa" has stood the test of time and holds good to-day.

Lister by his discoveries in antisepsis made possible the invasion of the abdominal cavity with impunity, and thereby opened up the field for the attainment of the hitherto impossible. It is only in the past twenty-five years that the abdomen has been opened so that intentional operative procedures upon the intestines might be performed. Before that time operations upon the bowels were only done in emergencies as the result of accidents, and as a forlorn hope. Less than fifty years ago, the rule was to do nothing, as nature was considered the better surgeon.

The mind of man has been ever active in the devising of ingenious devices whereby a fellow-being might be saved from the consequences of grave intestinal wounds, as is shown by the precursor of the Murphy button, when four monks of the thirteenth century first snatched from death a case of intestinal injury by inserting the trachea of a goose into the open lumen of the bowel. This was the

first authenticated instance of a foreign substance being placed in the interior of the gut for purposes of anastomosis. Since that time every conceivable substance of metal, bone, rubber, and vegetable matter has been employed to take the place of the goose trachea, known in history as the "Method of the Four Masters."

In 1730 we find recorded the first case of recovery following circular enterorrhaphy for complete transverse division of the bowel, when a surgeon by the name of Ramdohr inserted one cut end into the other and retained the parts by a single suture placed

Fig. 3.

in the convex border of the intestine; truly a remarkable recovery.

Since that time the development of the subject has been upon three lines, and we may divide the methods into three classes of operation: First class, methods where foreign bodies are employed in the lumen of the bowel to hold the ends together, and to act as splints to favor accurate approximation. Second class, by suture alone. Third class, by mechanical devices which hold the parts in apposition while the sutures are being placed, but which can afterward be withdrawn.

All three classes as perfected to-day are successful, but each has its disadvantages as well as its advantages, so therein lies the reason for the constant

Fig 4.

appearance of new methods and new devices, in each of which an approach to the ideal has been sought for.

First class: The principle in which a foreign body is placed in the lumen of the bowel to secure an accurate approximation of the parts, and to facilitate the introduction of sutures, finds its origin in the method of the "Four Masters" previously referred to. Senn, by his masterly investigations upon the healing of intestinal wounds, stimulated the work in this country, and in 1887 he presented his method of using decalcified bone plates to hold the cut ends of the bowel together. These had the advantage of being softened and gotten rid of by the action of the intestinal juices, so that they were eliminated after their usefulness as splints was over.

This method is not popular to-day, because of the trouble in preparing the plates, and the introduction of more handy substitutes. Different investigators have presented the same idea, using rings of catgut and rubber, plates and cylinders of cartilage, turnip, potato, chromicized gelatin, tallow, raw-

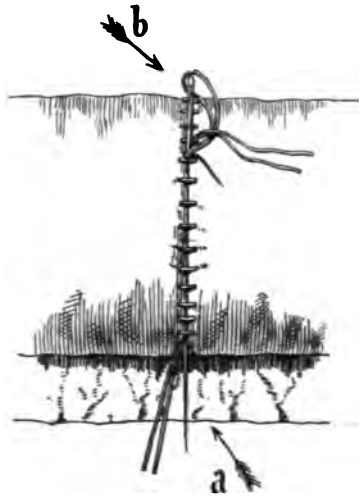

Fig. 5.

hide, rubber, cardboard and cork. The same objections that apply to Senn's original bone plates apply to all of these methods, chiefly that they are never ready, are difficult to prepare, and require unusual skill to apply them speedily and accurately.

It was not until Murphy of Chicago invented the button which bears his name, in 1892, that a means was found whereby the ends of the intestines could be accurately approximated, serosa to serosa, with great speed, and without the employment of unusual skill, that the whole problem was simplified and a

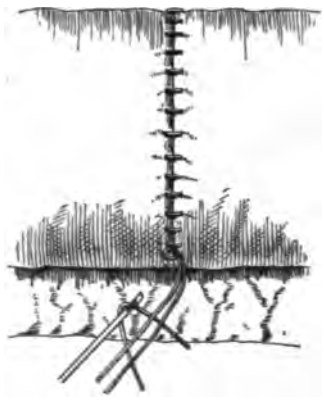

Fig. 6.

great advance in results was attained. The Murphy button is to-day the most used of all methods, which means that it has proved generally satisfactory. It owes its popularity mainly to its simplicity of application, and to the rapidity with which the anastomosis can be made by its use; two most important requisites to the success of any method. When it is used without reinforcing sutures, much time is saved, but of late years I think the majority of surgeons prefer not to trust to the button alone, but insert a row of sutures to insure the strength of

the union. This procedure naturally increases the amount of time required, and takes away one of its chief advantages, and places it on a par with other methods which depend upon sutures for their success. It is interesting to note that the advent of the Murphy button was not without severe criticism at the hands of acknowledged authorities. Senn wrote of it in 1893 as follows, "It is an exceedingly ingenious appliance, but its mechanism, as far as uniting the ends of the bowel is concerned, is no

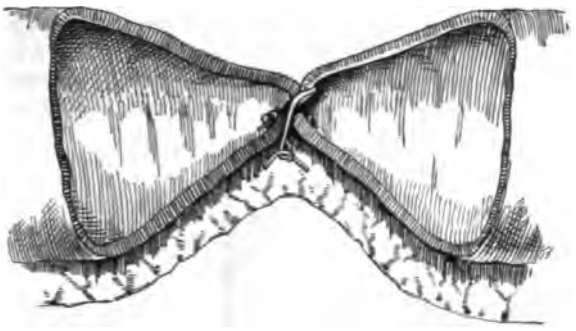

Fig. 7.

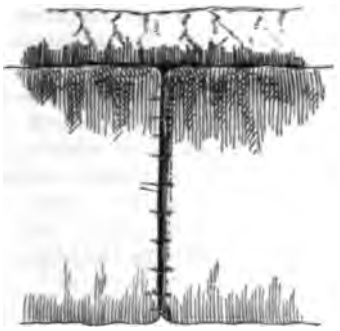
improvement upon the rings employed by Denan, more than half a century ago. Any instrument, suture, or ligature used in effecting the continuity of a wounded or a divided bowel that produces gangrene must be looked upon as a source of danger. As a means of end-to-end union of the intestine, the Murphy button is certainly inferior to Denan's procedure, because the lumen of the connecting part is not large enough as a temporary outlet for the intestinal contents." He quotes Keen, in the *Annals of Surgery* for June, 1893, as saying, "The button should be abandoned for intestinal anastomosis," and concludes, "If this warning of so eminent a surgeon foreshadows the final verdict of the pro-



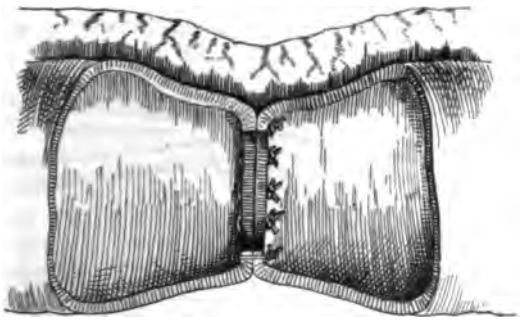


Fig. 8.

fession in regard to the use of the button for anastomotic purposes, it will never come into use in end-to-end approximation."

That Senn has been compelled to change this early opinion of the merits of the button is shown, if we refer to his recent work on "Practical Surgery" just issued, in which he says of it, "Of all the appliances as a substitute for suturing of intestinal wounds, the Murphy button has been used most extensively, and has yielded the best results."

The main objection to the Murphy button is the fact that a large foreign body is left in the canal, and this is a serious feature, as sometimes the button does not come away, but remains to cause intestinal obstruction.

Another objection is that the lumen of the button is very small, which predisposes to clogging of the aperture. As its liberation depends upon sloughing

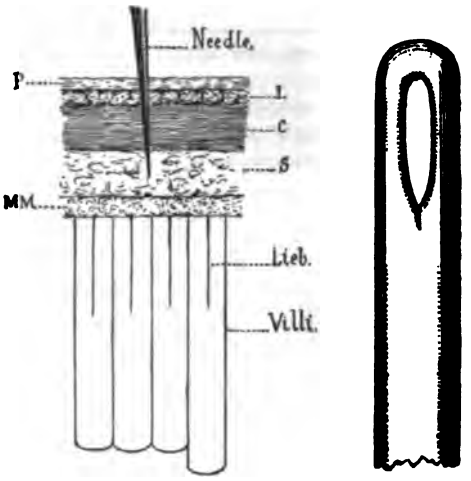

Fig. 9.

of the walls which are pinched within its opposing halves, a raw, unhealed surface is left on the interior of the bowel, which likewise has given trouble by becoming adherent or by causing contraction. Another objection is, that as the walls of the intestine often vary greatly in thickness, the button does not always fit properly, and then again the spring and catch of the button are liable to get out of order, especially when not made by the best instrument makers.

Second class: Methods where union is obtained by suture without mechanical aids, may be said to date from Ramdohr's application of a single stitch.

The glovers' stitch is the first suture recorded, but is abandoned. Since that time innumerable methods have been invented, but few have survived the

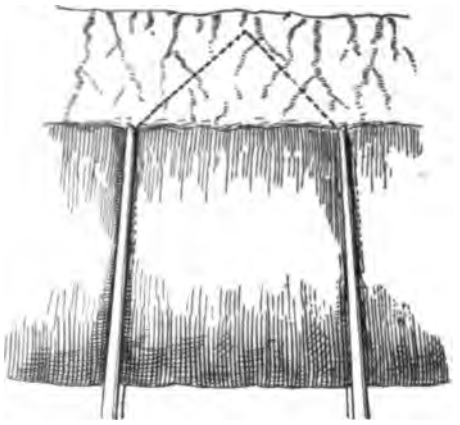

Fig. 10.

test of experience. The law of "serosa to serosa," as first demonstrated by Lembert, marked a change in the technique of suturing, and all methods to-day have the approximation of serous surfaces as their object.

The continuous overhand suture, applied after the principle of Lembert, is rapid but has marked disadvantages; namely, if one part becomes loose the whole is liable to become insecure; in tightening it, it is difficult to secure even tension all along the line; should the bowel contract, the whole suture may become loosened and the wound gape. Therefore it is not

safe to trust alone, but it may be used in combination with the Lembert stitch.

The Lembert suture is an interrupted stitch, and approximates the serous surfaces by picking up the peritoneum and muscular coats. Halsted, in recent years, has emphasized an important fact, first noted by S. D. Gross in 1843, that the submucous coat of the intestine is of a strong fibrous nature, and that to insure proper holding of the sutures the point of the needle must penetrate this coat.

The Czerny-Lembert suture is the Lembert stitch reinforced by a deep row approximating the mucous membrane.

The quilt or mattress suture recently devised by Halsted, is a most important advance. It is so

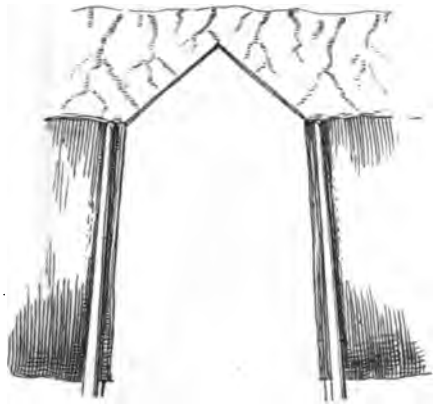

Fig. 11.

safe that a single row of stitches will suffice, thus obviating the danger of gangrene, which is sometimes caused by the double row of Czerny-Lembert sutures. It constricts the tissues less than the Lembert suture, and does not tear out so readily, if submitted to tension; furthermore it is more rapid of execution, as there are just one-half the number of knots to be tied.

In all the above methods the knots are tied on the peritoneal surface of the bowel. This has been always recognized as objectionable on account of irritation, the danger of capillarity should a stitch accidentally penetrate into the lumen of the gut, and the fact that the suture is likely to remain permanently.

Maunsell's method appeared in 1892, and it was a departure from previous methods, as the suture and the knots were here placed inside the lumen at the

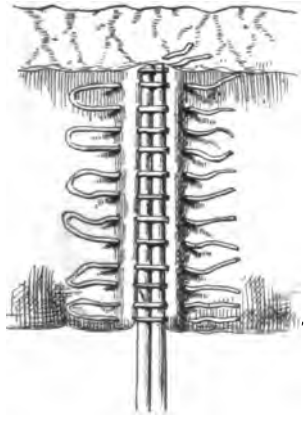

Fig. 12.

site of the anastomosis, but the closure of the longitudinal slit through which the ends of the bowel are inverted, must necessarily be closed with external sutures. This method affords a very secure union of the cut ends, as the whole thickness of the intestinal wall is penetrated by the stitch. Practically it has proved most successful, as instanced by a report of thirty-one cases, with but three deaths.

Third class: Methods wherein mechanical devices are used to facilitate the placing of the sutures, and which are afterward withdrawn, have been much advocated of late, and many clever instruments have been devised. Halsted's inflatable rubber bulb is one example of this method. The collapsed bulb is placed in the lumen of the bowel, the cut ends of which are held in apposition by stay sutures. The bulb is inflated to distend the bowel while the stitches are passed and tied, after which it is deflated and drawn out before tying the last stitch. A number of ingenious forceps have been invented to accomplish the same purpose, notably those of

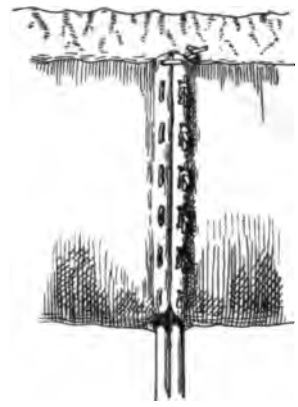

Fig. 13.

Mudd, Grant, Morrison, Lee, and especially the Laplace instrument.

The objection to rubber bulbs or cylinders is manifest when we remember how rubber deteriorates, and how easily an unintentional needle puncture would collapse the bag. The various forceps mentioned are complicated and frequently difficult to apply, yet under suitable conditions the method is a most admirable and successful one.

The aforementioned methods are illustrative of the three classes of operation, and may be said to be the standard procedures employed to-day in this branch of surgery, and with which you are doubtless familiar. I wish to present to you some new methods recently advocated, and shall speak of three, each belonging to one of the three classes. Each is claimed to overcome the objections advanced against the standard methods, and therefore are a nearer approach to the ideal sought for.

The first method I shall call your attention to belongs to the first class, whose most familiar prototype is the Murphy button. It is Harrington's

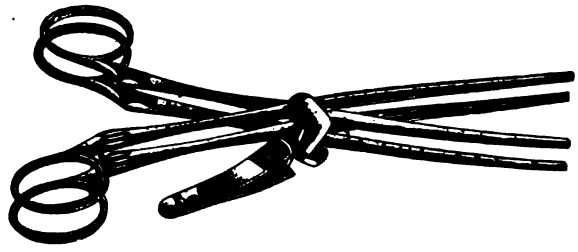

Fig 14.

segmented ring for intestinal anastomosis (see figure 15).

It was invented by Francis B. Harrington, surgeon to the Massachusetts General Hospital, and was published in the *Boston Medical and Surgical Journal* for November 6, 1902. It consists of a ring of aluminum made in four sections which are grooved to fit each other, and they are firmly held together by a small rod of steel which screws into two of the segments, and at the same time acts as a

convenient handle. The circumference of the ring is concave. A purse-string suture of silk or catgut is run around the cut ends of the bowel, as in using the Murphy button. The ends of the bowel are then slipped over the ring and the purse-string sutures firmly tied in the groove. Lembert, or Halsted's mattress, sutures are then placed to approximate the peritoneal surfaces of the gut. The handle is then unscrewed and withdrawn and a little firm pressure separates the ring at once into its four sections, which are small and easily passed by the bowel, thus having the advantages of the crushable cylinders of potato, turnip, etc., without their disadvantages. This ring has some of the good points of the Murphy button and the Laplace forceps, and is without their objections. It is much simpler and less expensive. The segments do not cause pouching of the intestine, as they weigh only from 10 to 25 grains, while the Murphy button weighs over half an ounce. The lumen is much larger than that of the button, and it does not depend upon sloughing for its liberation. It is quickly applied, as the handle greatly facilitates manipulation. The ring has been used in a number of cases of intestinal anastomosis with excellent results.

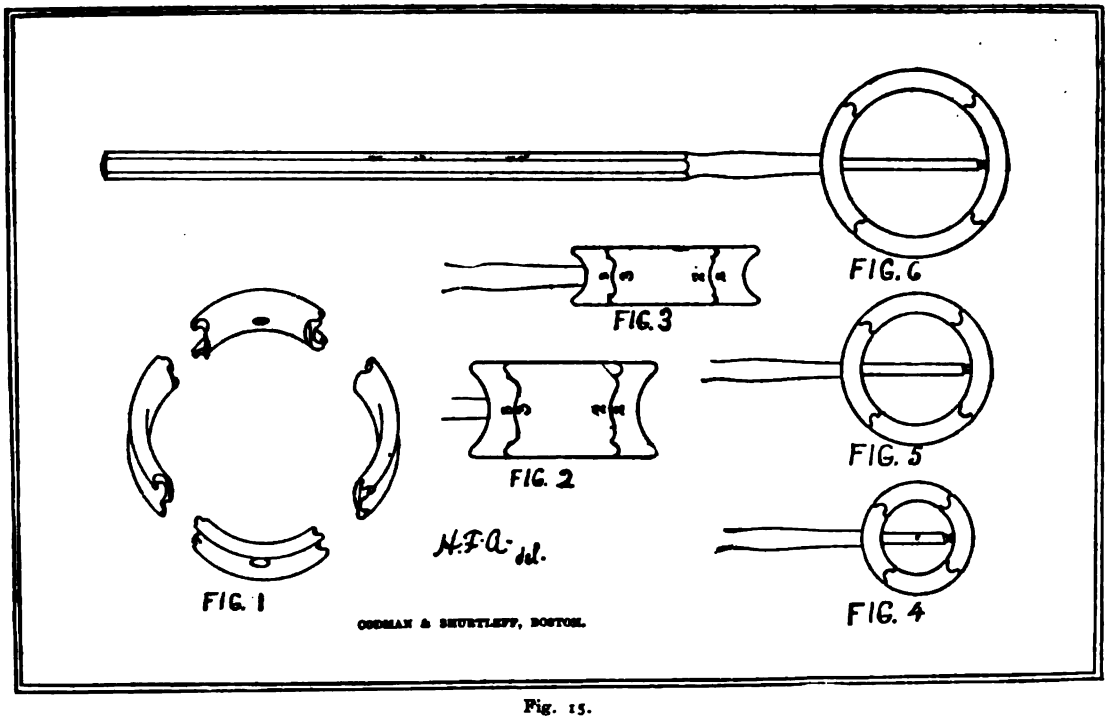

Fig. 15.

The second method of which I wish to speak is known as the "Connell Suture," and belongs to the class of operation in which no mechanical aid is employed. This ingenious method was invented by Dr. F. Gregory Connell of Chicago, and was first published in the *Philadelphia Monthly Medical Journal* for January, 1899. It was first employed in June, 1900, by Martin of Chicago, and was presented in an improved form with a report of nineteen cases and fifteen recoveries, before the American Medical Association in the summer of 1901, by Dr. Connell. This paper appeared in the *Journal of the American Medical Association* for October 12, 1901, under the title of "The Knot within the Lumen in Intestinal Surgery." Of all the methods belonging to this class of operation, it, theoretically at least, more nearly approaches the ideal than any other yet devised.

We have mentioned the great success of Maunsell's method, and noted that the success of that method was due largely to the firm union obtained by the sutures passing through the entire intestinal wall, and to the fact that all of the sutures and knots were upon the inside of the bowel, with the exception of those closing the longitudinal slit upon the convexity of the intestine, through which the cut ends were inverted while being sutured. It must be apparent that if we could find a way of placing all the sutures and knots upon the *inside* of the bowel, and at the same time do away with the longitudinal incision, which is necessary to enable us to place the sutures in the Maunsell operation, we would surely be approaching very close to the ideal. This is what is made possible by the Connell suture.

The resection of bowel having been made in the ordinary manner, the first stitch is placed at the mesenteric attachment of the cut ends. The needle is passed clear through the intestinal walls of both cut ends on one side of the mesenteric attachment and is returned through the walls in a like manner on the other side and is tied as is shown in figure 1, A. The ends of the suture are left long so as to make convenient stays for the assistant to hold.

The next stitch is passed in a similar manner, but at a point about one-third of the circumference of the bowel away from the first stitch (see figure 1, B). The ends of this stitch are also left long and the assistant now holds the bowel by the two stitches (see figure 2, A and B). Next, stitches are now placed in the space between suture A and B, and are tied and cut short, thus completing one-third of the anastomosis (see figure 2). In inserting these sutures, the needle penetrates both cut ends of the bowel at once, thus saving considerable time.

The second third of the circumference is closed in precisely the same manner as the first third (see figure 3).

The closure of the last third must be done in a somewhat different manner. While the stitches are placed and tied in exactly the same position, the needle must penetrate each wall of the gut separately as shown in figure 4.

It is apparent that no difficulty in tying the stitches on the inside of the lumen will be encountered until we come to the last stitch, as they are tied through the opening in the bowel not yet closed. But after the last stitch has been placed, comes the problem of tying it with the knot inside the bowel, and herein lies the trick of the Connell method.

The last stitch having been placed in position ready

to be tied, a threaded needle is passed, *eye* end first, between the approximated walls of the bowel, at a point nearly opposite the last stitch in the space between two sutures (see figure 5, a). The eye end of the needle, with its thread, is brought out of the aperture remaining to be closed by the last stitch (see b, figure 5). The ends of the last stitch are then passed through the loop of the threaded needle (see b, figure 5), and are drawn into the bowel, and out of it through the space in the walls at which the eye end of the needle first entered (see figure 6).

The ends of the last stitch are now drawn tight, closing the final opening, and bringing the opposite sides of the bowel in contact with each other, while the stitch is tied and cut (see figure 7). The knot is then slipped into the lumen of the bowel through the space between the stitches, and the seemingly impossible has been accomplished (see figure 8).

This method is difficult to describe, but is simple to grasp when once seen.

The chief advantages of this method over others of this type are, in the very firm union of the serous surfaces of the bowel, that practically none of the suture material is exposed on the peritoneal surface, therefore obviating the danger of capillarity, that the suture material eventually works its way into the lumen of the intestine and is thus entirely gotten rid of, and that no incision in the wall of the bowel is necessary to accomplish it, as is required in the Maunsell method.

In the Maunsell operation the anastomosis is made with an overhand stitch, and there is always a possibility that the cut ends may slip by each other, so that the serous surfaces are not in perfect apposition. In Connell's method this is impossible. It is a decided advantage to have no sutures on the peritoneal surface, as they sometimes cause irritation and may eventually be the cause of a fecal fistula. The avoidance of an incision in the bowel is a decided improvement, of course. Furthermore, Connell demonstrated in his article on "The Knot within the Lumen" that it is practically impossible to place a Lembert, or Halsted mattress, suture without perforating the entire intestinal wall. Halsted showed that, in order to get a firm union, it was necessary to penetrate the tough and strong submucous coat, and all operators recognize that fact to-day. In his article he illustrated the relative thickness of the various coats of the intestine by a picture which magnified the wall of the bowel about thirty-two times (see figure 9), but as Connell rightly points out, he failed to magnify the needle in the same proportion as the rest of the illustration. In figure 9 is shown the size of a No. 8 needle magnified the same number of times as the intestinal wall in this picture, and it must be readily apparent to all that the task of picking up the submucous coat with any surety of not penetrating the mucosa is a practical impossibility. The submucous coat is estimated as being $\frac{1}{100}$ inch in thickness, while the No. 8 needle has a diameter of $\frac{1}{40}$ inch. Also, it is important to remember that in the duodenum, Brunner's glands, which, of course, are in direct communication with the intestinal lumen, are situated in the submucosa.

Therefore there would seem to be no advantage to be derived by using Lembert or Halsted sutures, as they, in practice, do not avoid penetration of the bowel and the dangers of capillarity.

Over a year ago the Connell suture had been employed nineteen times with fifteen recoveries, and it must have been used many times since. Its further employment will, undoubtedly, become popular as its merits are known and its technique mastered.

The third method that I wish to present is that of O'Hara forceps, which belongs to the class in which mechanical aids are used. This instrument was first presented by Dr. M. O'Hara, Jr., of Philadelphia, in April, 1900. It consists of two slender clamp forceps held together by a serre-fine (see figure 14).

The technique of the method is extremely simple. Each forceps is clamped on the gut at the exact points where the intestine is to be resected (see figure 10). The intestine is cut away close to each forceps (see figure 11), and the two forceps are then approximated and fastened together with the serre-fine clamp. Halsted mattress sutures are then placed so as to bring the walls of the intestine together over the forceps (see figure 12), and when one side has been completed both pair of forceps are turned over and the other side is sutured in the same manner. The sutures being all tied, the forceps are therefore completely buried (see figure 13). The forceps are then unlocked, and each one is withdrawn through the small opening left, which is closed by a stitch.

The advantages of this instrument are, that they are rapid of application and simple in construction; that one pair of forceps will answer for any size of intestines, thus doing away with the necessity of various sizes of Murphy buttons and Laplace forceps; that no preliminary clamping or ligating of the bowel is necessary, and last but not least, that they avoid contamination with the interior of the gut, as all the manipulation is exterior to its lumen. This last is an advantage which no other method possesses. With the foregoing recent methods, I have had personal experience with the O'Hara forceps only.

Last summer I resected seven inches of ileum with their aid, in a patient who came into my service at the Post-Graduate Hospital, with the following history: Mrs. A. S., age twenty-six years, married seven years, perfectly healthy until the birth of her only child five years ago. Her labor was difficult, requiring forceps, and was followed by puerperal sepsis, which resulted in the formation of a tuboovarian abscess on the right side. This abscess eventually pointed in the right inguinal region above Poupart's ligament, and although it was opened and curetted by her physician, it had resulted in a sinus, which was discharging pus freely at the time I first saw her. Her general condition was one of misery, as she suffered constant pain. At times she had a profuse discharge of pus from the rectum. Examination disclosed a subinvoluted retroverted uterus, firmly bound with adhesions, and a mass in the right side, the size of a duck's egg. A probe passed into the inguinal sinus entered directly into this mass. Before opening the abdomen, the inguinal sinus was sealed with gauze and collodion to prevent contamination. Extensive omental adhesions were encountered, and the tuboovarian abscess was exposed with considerable difficulty. The vermiform appendix with the caput coli and two loops of ileum were densely adherent to the wall of the abscess. An appendectomy was next done, and the head of the colon released. One loop of intestine communicated directly with the abscess cavity by an opening one inch in diameter, and this was closed with mattress sutures. The other loop of bowel was constricted, and had several perforations, so that I deemed it unwise to leave it. This loop, seven inches in length, I resected with the aid of the O'Hara forceps. The walls of the abscess were dissected out and the opening into the inguinal sinus was closed. Vaginal drainage was made. The patient made a rapid and uncomplicated re-

covery, and is entirely well to-day, having gained fifteen pounds. The ease with which I was able to make the resection with this instrument and the satisfactory result obtained fully confirm the claims that have been made for it.

These recent methods are certainly worthy of attention, and as they overcome the recognized disadvantages of the standard operations, they must be looked upon as a decided advance. Doubtless each operator will prefer the method to which he is most accustomed, but it is not wise to depend on one method alone, as the circumstances under which we are called upon to make an anastomosis are very variable [illegible]

The surgeon surely has a variety to choose from in these three methods, but whether he prefers the crushable ring or the O'Hara forceps, he should certainly include the Connell suture in h s repertoire, as it is necessary that he have one method at his command when only a needle and silk are needed to accomplish an anastomosis, as the emergency may unexpectedly arise when no mechanical aids are at hand.

210 West Fifty-ninth Street.

## THE PHYSICIAN AND THE OPHTHALMOSCOPE.

By FRANCIS VALK, M.D.,
NEW YORK.

At the last meeting of the State Medical Society held in Albany, our retiring President, Dr. Henry L. Elsner, in his closing address, "A Modern Diagnosis," used these words, "An instrument of precision too little employed by the general practitioners is the ophthalmoscope, for the introduction of which the memory of Von Helmholz will always be revered."—"It gives information regarding the existence and nature of pathological conditions elsewhere than in the eye which is often obtainable in no other way." As I listened to his argument on the use of the ophthalmoscope I asked myself the question, How many physicians know how to use this extremely valuable instrument? Why do they not use it? Can its use be so demonstrated to them that they may use it?

These are questions to be answered partly by the physicians themselves, but the last must be answered by one somewhat familiar with the use of the ophthalmoscope and with the advantages it may present to the physician in the diagnosis of many conditions that arise in general practice, either that it may elucidate some unexplained phenomena or confirm some previously suspected conditions.

It goes without saying that every physician should make himself as fully competent as possible in the diagnosis of all general diseases, with their complications and their sequela. In the use of all other instrumental aids, as the stethoscope, etc., the physician does inform himself as thoroughly as possible, yet in the use of this instrument, one of the best for objective diagnosis of disease, he seems to have left it in the hands of the specialist; depending possibly on a consultation or passing the matter to one side depending solely on his other objective and subjective signs.

There are few instruments in the hands of the physicians that can give as useful information in the diagnosis and prognosis of disease as that of the ophthalmoscope, nor is there one that can be relied upon so implicitly. The findings of the ophthalmoscope are so obvious and correct that they leave no doubt as to the condition of the fundus and the systemic conditions that these findings may indicate. Furthermore, as Gowers well says, "We examine the artery to its termination and the commencement of a vein with the blood circulating in each; the termination of a most important nerve which, from its close proximity to the brain, undergoes significant changes in various disease conditions of the brain and in affections of all other parts of the nervous system; and a nervous structure, the retina and a vascular structure, the choroid, which also suffer in a peculiar way in many general diseases." Is not this matter important enough for a careful consideration?

I do not expect that the general practitioner will ever become so far proficient as to readily detect all the most delicate changes that are sometimes presented by this beautiful system of vessels, nerves, and tissues of the eyeball, yet I do believe that with reasonable experience in the use of this instrument the physician may so perfect himself as to recognize the most important changes in these delicate structures of the eyeball indicative of or associated with some systemic disease. What can be more useful than the picture presented by the appearance of the termination of the optic nerve in any obscure disease of the brain or that of the retinal vessels and the retina itself in diseases of the kidney? Do we not know of cases of Bright's disease in which the first correct diagnosis has been made when the eyes have been examined with the ophthalmoscope? Tuberculosis may be diagnosed, or at least confirmed, with the ophthalmoscope by the appearance of the fundus, as it shows the characteristic tubercles in the choroid, and in doubtful cases of acute miliary tuberculosis may confirm the diagnosis. It is not always possible to refer these cases to those who are engaged in this special field of medicine and one who can use this instrument—even in a comparatively limited manner—will be much more than compensated from the instruction and the information it will give him. The brief time it may require to learn the method of its use in a practical way is not very great.

How often have I heard the answer to the question, Have you an ophthalmoscope? Yes, but I never use it; but why? Why does the physician possess this instrument and yet not use it? I think I can answer this question in this way: Because when he commenced the study of ophthalmoscopy in the textbooks he found it presented so many details and so many complications that the instrument was soon laid aside, simply to be remembered in the possession of its owner, but not to be used. It is my hope that this subject may be presented in a very simple manner, by one partially familiar with its uses and advantages, which is the object of this paper, and I would present it by the common-sense method, so that it will be useful to the physician, and leave the more complicated uses of the instrument to the specialist.

Before proceeding further let me describe the instrument. What is it? It is simply an apparatus by which we may place the examiner's eye in the path of the rays of light as they come from the background of the examined eye when illuminated by reflected light.

To see an object we must have the rays of light pass into our eyes in certain directions, either parallel or divergent. Now the rays coming from an examined eye are either parallel, divergent, or convergent. To the second condition—divergent rays—our eyes are readily adjusted and we have a perfect image on the retina of the examiner, the fundus being easily seen. The parallel and convergent rays cannot be focussed on the retina—and here is one of the trials of the beginner—except under special conditions, but they can be

easily made divergent and so become useful for the vision of the examiner. Then our instrument is a mirror to illuminate the examined eye and a disk of lenses to so bend the emerging rays that they may focus on the retina of the examiner.

To illuminate the eye we require a good steady light—the Argand burner with oil or gas is the best—a slightly concave mirror to concentrate and reflect the light and a handle to direct the reflected rays, within the eyeball, directly through the pupillary space. If we now place the examiner's eye in the center of the rays coming from the examined eye—that is, behind the aperture—as the retina is illuminated, he will be able to see the details of the fundus if the outcoming rays are divergent. If not divergent we cannot see the fundus clearly, and we must make them so by placing suitable glasses behind the aperture. It can be readily understood that if the examiner's eye receives these rays and can focus them on the retina, they must there form a picture that will correspond with the object from which they proceed. In other simple words, the ophthalmoscope enables us to look into the eyes of our patients and to see the condition of the eye-ground, either in health or disease. Such is the simple purpose of the ophthalmoscope, seemingly very easy, but I will point out the difficulty that may arise and then show the usefulness of the instrument.

It has been fifty years or more since the ophthalmoscope was first used to see the interior of the eye, but to Von Helmholz we owe all reverence for his introduction of this instrument in 1851, and those of to-day are the same in principle, only differing in the mechanical parts, as when the instument was first used. I do not propose to enter into the subject of the estimation of the refraction of the eye, but only how to see the background or retinal field; what it looks like and what are the essential changes that we should be able to see, to know, and to appreciate. Now the textbooks tell us to look through the aperture of the ophthalmoscope as if we were looking toward infinity or in the distance with the accommodation at rest, etc. This is all very true, but it requires a vast amount of practice to master just that; no beginner can do it, nor is it essential, and moreover it is only useful to the specialist. I shall then try to inform you as to the use of the instrument as needed in the hands of the general practitioner. Let us accept the statement that one is utterly ignorant of the method of using the ophthalmoscope, but wishes to understand its use in the diagnosis and prognosis of certain diseases of the general system. How then shall he use the ophthalmoscope so that he may gain this practical knowledge? Place the light—let me say at once that too bright a light is not necessary for the appreciation of the most delicate changes at the fundus—behind the patient, about one foot distant from the eye, on a level with it and to the right or left according to the eye to be examined; seated now on the side of the eye to be examined, the ophthalmoscope is placed before the corresponding eye of the examiner and he looks through the small opening or aperture. If possible, it is best to keep both eyes open, but for the purpose we have in view, one may close the eye not used if by so doing it will assist him in the examination. Now reflect the light from the lamp or gas-burner into the patient's eye and we find the pupil changes from its natural blackness to that of a bright orange red. If not so, we must proceed to a more detailed examination of the anterior part of the eye, as the cornea and lens. To do this, we place the lens marked + 6. in the disk, at the aperture and we move nearer the patient until we are within the focal distance of the lens—about five or six inches—when we will see the anterior part of the eye mangified and can readily detect any opacity or changes that may appear on the cornea or lens, showing generally as black spots on the bright orange red color of the pupillary space. This examination may indicate incipient cataract, iritic deposits on the capsule or, if there is complete absence of the pupillary reflex, some very serious condition of the interior of the eye-ball. To resume, if this portion of the eye is found to be perfectly clear, we now proceed to examine the deeper parts or fundus. Removing the convex lens and again looking through the aperture, with the reflected light directed into the pupillary space, we now attempt to see the background or fundus of the eye—in other words, the nerve, retina, vessels, the choroid, etc. But just here comes the great difficulty which all examiners meet in their *first attempts* to examine the eye. This is due to the direction of the rays of light coming out from the examined eye and the inability of the examiner to control the action of his own accommodation. We make an effort to look at something very close to us on account of the proximity of the patient's eye and so we exert a certain amount of accommodative power, preventing the formation of a distinct image on our own retina. To obviate this difficulty, so common to beginners, we must place at the aperture one of the concave lenses marked with red figures on the disk. This will neutralize the action of our own accommodation, will make the rays of light divergent and then the details of the fundus will rapidly come to view. Now, having mastered this instrument to the point where you can begin to see the fundus, you must know what you see and what to look for, both in health and disease, so that you recognize such pathological conditions of the fundus that may point to some systemic condition. If you will attempt to make this examination on the eyes of your patients that have no eye troubles, young people with large pupils, you will soon appreciate what is the appearance of the normal fundus, with the arteries, veins, and nerves. With this mental picture before us we can readily see any pathological changes that may have taken place. Before proceeding further, let me state, inasmuch as the pupillary area is not always the same in every eye, and when very small it is very difficult even for an expert to see anything except the red reflex, then you are justified in using a weak mydriatic to dilate the pupil. Atropine will not do for this purpose, as it impairs the sight too long. Cocaine, 4 per cent., or homatropine, one-fifth of one per cent., will be the best dropped in the eye about twenty minutes before we are ready to begin the examination. Either one of these drugs will dilate the pupil in a short time and will make your examination much easier, while the effects of the mydriatic will pass off in about twenty-four hours.

All these conditions now being at our command, the next question arises, What is the normal appearance of the fundus or background of the eye? and in the words of Haab, "I cannot too strongly advise the beginner to study the normal eye as often and as thoroughly as possible."

We first note the color of the eye-ground; this will appear very different even in perfect health, according to the individual, as blonde or brunette. Brunettes generally present a much darker eye-ground than blondes. This difference is chiefly due to the amount of pigment in the retinal layer,

the pigment epithelium. This pigment is also in the choroidal layer showing as dark spaces between the choroidal vessels, and in the negro the dark spaces and the numerous choroidal vessels are very often seen, while in the albino, with little or no pigment, the vessels of the choroid will appear red on an almost white background. In the region of the macula or yellow spot—the position of most acute vision—always found outward toward the temples from the nerve entrance, we find the pigment color darker and in many cases a small spot in the center. This pigment is also seen about the entrance of the optic nerve, forming the choroidal ring, dark masses irregularly placed, but seldom, if ever, extending completely around the nerve. The nerve entrance is quickly seen, being so prominent as a large round space, apparently in the center of the eye-ground. It presents a grayish-white color, seemingly semi-transparent, and the central part whiter from the dipping inward of the central nerve fibers. If the central part is very large and deep, the lamina cribrisa may be seen as a large, white network in the nerve entrance. This nerve entrance or papilla may be round or slightly oval in any direction, and in a condition of health its surface does not extend beyond the plane of the retina. The retina itself in health cannot be seen except in some cases by the most practised eye. The general appearance of this eye-ground presents to the examiner's eye a peculiar appearance, as of a very small irregularly figured carpet, somewhat like a mosaic of small light and dark spots; this is called the *stippling of the retina*. This is very important and should be carefully studied, as its presence or absence must indicate the condition of the retina. The slightest changes are shown by the blurring of this delicate network of pigment, which indicates some pathological condition either in the eye itself or the parts behind it. The arteries of the eye-ground consist of the branches of the central artery of the retina, which pass out from the nerve and dividing into smaller arteries extend outward over the entire retinal field to the anterior part of the eye-ball; similarly, the veins of the eye-ground have the same arrangement, are darker in color and empty into the central vein of the retina. We can recognize the arteries by their lighter color and the white line that runs along the center of each vessel, while the veins present a much darker color, the line along the center not being so prominent. All these vessels have a straight course, being slightly curved, and they can be distinctly traced to the periphery of the retina. Any irregularity in their course or blurring of their outlines is probably due to some retinal changes Pulsation in the veins on or near the nerve entrance, may be readily seen and has no special significance, but if seen in the arteries is serious. The diagnosis of this condition is very difficult and would carry us beyond the scope of this paper. For a more complete description of the normal eye-ground I must refer you to the many textbooks on this subject, but I have described the most important details of the appearance of the normal fundus as seen with the ophthalmoscope, in order that we may become familiar with this picture from the examination of the eye in health so as to appreciate the changes that take place in disease as shown by the retina nerve and vessels.

Because of their frequency and their importance in the diagnosis of disease, there are two conditions of the fundus of the eye that will always have special interest to the medical profession. I refer to retinitis in its many manifestations and what is commonly called "choked disk." Retinitis, inflammation of the retina, covers a vast variety of changes in the back part of the eye, readily seen by the expert with the ophthalmoscope. The general practitioner cannot see all the minute changes, yet with reasonable care he can appreciate the important changes that may indicate some local or systemic disease if he becomes familiar with the appearance of the normal fundus. Now inflammation of the retina becomes the most important change, because it is frequently present in so many other systemic diseases that may be first noticed from the complaints of failing vision, as if there was a veil or blur over the page when reading. According to Jacobson (*New York Medical Journal*, July, 1901), inflammation of the retina occurs in 10 per cent. of the cases of Bright's disease, and is known as albuminuric retinitis. Its significance is very important, as it is well known that when these changes take place in the retina the possible duration of life is seldom more than two years.

I made the diagnosis of Bright's disease with the ophthalmoscope in the case of supposed hysterical amblyopia and in three weeks from that time the patient, a young girl, passed away. The importance of this examination must be obvious to all, and if we have the pupil dilated with any brief mydriatic, and retinitis is present, then, as we look into the eye with the ophthalmoscope, we will see a great difference in the appearance of the retina from that of the normal. The edges of the disk will not be clearly seen; the veins will be dark, tortuous and dilated; the arteries, partly covered by the swollen retina, cannot be followed to the periphery and seem to be covered by white masses, like clouds, that are partly due to exudation and œdema of the retina. Then we find various dark, irregular spots, small and large, scattered about the retinal field, due to hemorrhages from rupture of some of the small vessels of the retina. In some cases these hemorrhages may be very large and in others very few or even entirely absent. White patches about the retina are frequently seen, in which we note that the edges are not very clearly marked, but shade off into the retina and the small blood vessels seem to pass through them. Fatty degeneration of the retina is also present and shows itself as a peculiar stellate appearance in the region of the macula or yellow spot. These minute spots are arranged in rows, radiating outward from the center of the macular region, not always perfect, as they may be absent on one or the other side, but when present with the other appearances are almost positive evidence of kidney disease. Knapp states that this degeneration of the retina may be seen in tumor of the brain, but I have not been able to see any cases yet that were not associated with albumin in the urine. The swelling of the retina may extend so as to involve the nerve-head or disk, with blurring of its outline and reddening of its surface; in advanced cases this swelling may resemble "choked disk" or papillitis, but the presence of the stellate figure in the region of the macula, the white patches and the hemorrhages will confirm the diagnosis of Bright's disease.

I do not know of any more important use of the ophthalmoscope to the practitioner of medicine than the diagnosis of the condition of albuminuric retinitis. The changes that may be shown in the early stages of this disease may present a slight congestion and tortuosity of the vessels, with blurring of the retina and the edges of the disk; this condition associated with diminished vision would lead us to suspect diseases of the kidneys and at a time when it may be amenable to treatment; but when we have the characteristic picture as presented, then we can only say that the prognosis is very grave, with probably

a fatal result in less than two years. It has been claimed by Pooley that the ophthalmoscope will assist us in the diagnosis of the albuminuria of pregnancy and if present is an indication of premature delivery, but I have had no experience with these cases, and without other signs should prefer to wait.

Choked disk or papillitis: Under this heading we may consider most of the inflammatory changes of the optic nerve or papilla. The ophthalmoscopical appearances of the condition may be readily understood when we consider how prominent the disk is, the normal appearance of the disk, its distinct circular outline and the branching outward of the vessels from the center. Now in choked disk we have an almost complete disappearance of all the characteristics of the normal disk, and on examination there is seen a distinct swelling of all the nerve fibers, which seem to stand out in the vitreous body, covering over parts of the blood vessels and then shading off, as it were, to an almost normal retina. Such is the simple picture of the choked disk and the appearance it usually presents at the ophthalmoscopic examination; but in some severe cases the swelling of the nerve-head is much more extensive, the vessels very tortuous, with extensive hemorrhages throughout the entire retinal field. To the expert with the ophthalmoscope this swelling or extension of the nerve-fibers into the vitreous may be measured, giving about .34 m.m. to each dioptre of refraction, so that he can note any increase or decrease of the elevation. Is not the diagnosis of optic neuritis or choked disk very important in the practice of medicine, as it is one of the important signs of an abscess or tumor of the brain, a sinus thrombosis and other inflammatory systemic conditions?

Optic Nerve Atrophyy: In tabes and other conditions where we have a diminution of the visual power, dim sight, the opposite condition to that of choked disk is found. Here we have all the details of the fundus and the nerve-head very clearly shown, but the natural soft color of the disk has changed to a hard, white or slightly bluish color. In tabetic atrophy the optic nerve has a pearl gray color. The edges of the disk are very sharp and clean cut, the lamina cribrosa shows as an interlacing of the nerve-head, and all the vessels appear much smaller than normal. In the gray atrophy of tabes the prognosis, as to any restoration of sight, is very serious, as they generally pass on to complete blindness.

Amblyopia, or blurred vision, due to atrophy of the optic nerves, as shown by the ophthalmoscope, and caused by the abuse of alcohol and tobacco, is probably more amenable to treatment and the prognosis is not so serious. This condition is more apt to affect the central nerve fibers or those supplying the macular region, and this is shown by a peculiar whiteness of the disk in the lower outer quadrant. Here we find the evidence of atrophy from the central scotomata, or blindness in the center of the field of vision; and conversely, in the tabetic atrophy the blindness commences in the outer part of the field and extends toward the center. I have some doubts about the atrophy of the nerve being caused by tobacco alone, but when we have the condition of alcohol and tobacco used in excess, and when the use of toxic drugs has been abused in early life, then I think they may bring about an atrophy of the optic nerve fibers. This may possibly be controlled by the stoppage of these pernicious habits, the use of strychnia by hypodermic injection and, in some cases, the iodides. I have never seen complete blindness from this *amblyopia ex abusa*.

Choroiditis: Changes in the appearance of the fundus of the eye are frequently seen as large white plaques with spots of pigment on the edges, and scattered about the retinal field are many pigment deposits looking very much like bone corpuscles. The retinal vessels are seen to pass over these white spaces without any deviation, showing that they are not involved in the process. This appearance is due to an inflammation of the choroid that may have been active but is now the result of a previous inflammation. In the acute stages of exudative choroiditis we have an infiltration of the choroid with exudation that hides the retina and through which the retinal vessels seem to pass. As resorption takes place the exudate disappears and the choroid presents these atrophic spots. Suppurative choroiditis is very serious and is generally metastatic. Bull states that he has seen several cases of infectious choroiditis due to *la grippe*, in which the ophthalmoscope gave a most startling picture, with ultimate destruction of the sight. This septic choroiditis is also met with in typhoid and other fevers, in pyæmia, in meningitis, and in puerperal septicæmia. The amaurotic cat's eye or pseudogliomata is a mild form of suppurative inflammation of the choroid, showing as a whitish or yellow reflex, deep in the eye, the pupil dilated and the tension of the eye decreased. This condition must not be mistaken for a true glioma of the retina that is always associated with increased tension of the eye-ball.

Embolism of the central artery of the retina may be the first indication of an endocarditis. This is well shown by the whitish color of the retina about the center, probably due to an exudation. The vessels are indistinct and in the center of the macula a cherry red spot is seen. This is a typical picture, and is only seen, as far as I know, in this condition and in the peculiar disease known as amaurotic family idiocy.

Hemorrhage into the retina is frequently seen, and if without any signs of inflammation would indicate an increased blood-pressure, disease of the retinal arterial walls, or some morbid states of the blood. In old people it shows a weakness of the arteries. These hemorrhages will show with the ophthalmoscope as dark red spots of various sizes and in many parts on the retinal field, some of them very minute and others very large. In diabetic retinitis very small hemorrhages may be seen, but generally only in one eye; and also in the diagnosis between chlorosis and pernicious anæmia as these hemorrhages are not seen in the first-named disease, but are frequent in the latter.

Glaucoma with increased tension of the eye-ball and diminished vision. The ophthalmoscope will show a cupping or pushing backward of the entire disk so that the blood vessels tip sharply at the edges and appear indistinct in the center. This condition is generally seen quickly with the ophthalmoscope and should not be mistaken for atrophic changes in the disk.

The use of the ophthalmoscope in the diagnosis of all the many changes that occur at the fundus would carry us far beyond the scope of this paper, so I have only considered those most useful to the physician.

I do not expect that all physicians will become so proficient in the use of this instrument, from a careful study of this paper, as to use the ophthalmoscope with all the skill of an expert. It requires constant application and experience even to master these details, but on the other hand, careful study and practise of the method I have endeavored to convey in this paper will soon enable one to see, to know, and to appreciate the appearance of the healthy background or fundus of the eye, and seeing and knowing this we may readily appreciate any changes that have taken place; that is to say, the pathological

condition of the retina and its adjacent structures and the systemic disease that is the prime cause.

It is impossible to describe the many conditions of the eye-ground that may be seen with the ophthalmoscope, nor is it necessary in a paper of this import. The diagnosis of all the many changes that may be of pathological interest must come from one who is fully competent to use the instrument in all the various conditions of the eye and the correction of its refraction, but I trust that I have made some suggestions that may be of service to the physician in his work. In closing, I again turn to the words of Elsner, "We do not contend that the general practitioner must of necessity become an expert in the use of the ophthalmoscope, but we believe that he must depend on its revelations, if he would early recognize certain diseases of the brain, arterial degeneration and renal complications."

## THE CYSTOSCOPE; ITS INDICATIONS AND CONTRAINDICATIONS IN GENITO-URINARY DISEASES.

By FOLLEN CABOT, M.D.,
NEW YORK.

VISITING PHYSICIAN, CITY HOSPITAL; ATTENDING GENITO-URINARY SURGEON, PRESBYTERIAN HOSPITAL DISPENSARY; INSTRUCTOR IN ENDOSCOPY AND CYSTOSCOPY, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

AND

HENRY G. SPOONER, M.D.,
NEW YORK.

ASSISTANT GENITO-URINARY SURGEON, PRESBYTERIAN HOSPITAL DISPENSARY; CLINICAL ASSISTANT IN GENITO-URINARY DISEASES AND INSTRUCTOR IN ENDOSCOPY AND CYSTOSCOPY, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In this article we wish to demonstrate what can be expected and what can not be expected from a cystoscopic means of exploration. We intend, also, to explain how to make a good cystoscopic examination, and also, from personal experience, to point out some of the stumbling-blocks to be avoided. We wish to show in what cases the cystoscope is useful, indispensable, or harmful. The cystoscope most frequently employed is that of Nitze. Nitze, by inventing the cystoscope and by his investigations on this subject, deserves one of the foremost places among those who have helped make an accurate diagnosis of genito-urinary diseases possible. It will not be necessary in this paper to give a detailed description of the many modifications of the cystoscope made by Brenner, Fenwick, Boisseau du Rocher, Guterbock, Albarran, and F. Tilden Brown. As the student of medicine must learn to use the laryngoscope and the ophthalmoscope, so must the student of genito-urinary diseases learn to use the cystoscope—as the accurate diagnosis of so many conditions of the bladder is impossible without this means of exploration. During the past year we have been using the cystoscope in our clinic at the Presbyterian Hospital with most satisfactory results. The results of the work done by cystoscopic examination, with the report of interesting cases from the clinic, will form the material for another paper by us later on.

Through the use of the cystoscope, we have been able to make an absolute diagnosis when patients have wandered from clinic to clinic, and left in a state of complete ignorance as to what was the matter with them. We must not expect too much of any one means of exploration. First, we must take down accurately the past history of the patient; then, we must proceed to the physical examination of the urinary and genital tracts—we must study the condition of the urethra, the bladder, and the kidneys; we must examine the testicles, the prostate, and the seminal vesicles. We do not agree with Dr. Willy Meyer, who says that after the surgeon has taken the general history and examined the urine, the first instrument that one must take is the cystoscope and not the sound. In order to make a successful cystoscopic examination, four conditions are necessary: (1) That the urethra must be sufficiently large to admit of easy passage of a sound of the caliber 24—French scale. (2) The bladder must be sufficiently tolerant to contain at least 90 to 120 grams of fluid. (3) The wall of the bladder must be transparent and remain transparent during the examination. (4) The prostate gland, if much enlarged, will interfere somewhat with our examination; therefore, before using any urethral instrument, we should make a rectal exploration to determine the condition of the bladder neck.

As the irrigating cystoscope of Nitze has the caliber 24 French scale, we have found that the urethra must permit of an easy passage of a rubber bougie 24 or 25. When the urethra is contracted, it must be dilated to this extent. When one is obliged to make an effort to insert the cystoscope into the bladder, one increases the discomfort of the examination, and often causes a bleeding which clouds the lamp. As enlargements of the prostate gland are nearly always on the inferior surface of the wall of the urethra, they seldom render any serious difficulty to the passage of the instrument. Even in cases of very large hypertrophies of the prostate gland, we have been able to pass the instrument by inserting the index-finger into the rectum, pressing the beak of the instrument against the upper urethral wall.

The bladder must be sufficiently tolerant to hold at least 90 to 120 grams of liquid. As it is necessary that the lamp be illuminated in the interior of the bladder without its touching the walls (when the lamp touches the vesical wall a blur occurs), it is a good plan to always have the bladder equally dilated. We have usually injected 150 grams of a two-per-cent. solution of warm bori-cacid solution. In most cases in which the bladder will not hold this amount of fluid, the cystoscope cannot be used. However, a number of means have been tried to increase the bladder capacity. Cocaine has been used for this purpose, but we must recommend the greatest caution in its use. While a healthy bladder does not absorb, every one admits that the pathological bladder and the mucous membrane of the urethra absorb to a very considerable extent. But 10 or 15 centigrams of a ten-per-cent. solution of the hydrochlorate of cocaine can be injected into the bladder without great danger. Where the injection of cocaine has not rendered the vesical capacity sufficiently great, the patient can be put under the influence of a general anæsthetic. However, it is often necessary to press the anæsthesia very far in order to make the bladder sufficiently tolerant, and often bladders, acutely inflamed, will not react even under chloroform.

The third condition necessary to make a good cystoscopic examination, is the transparency of the walls of the bladder. To obtain this condition the bladder is washed with a two-per-cent. solution of boric acid. When the bladder bleeds, the examination is rendered much more difficult. We must see that the blood does not cloud the prism of the instrument. In these cases an irrigating cystoscope must be used—and irrigation must be continued during the examination. In cases of hemorrhage of the bladder or urethra, adrenalin chloride 1-5,000 is an effective remedy, and should be used just before introducing the cystoscope.

Before using the cystoscope, which should be placed in a 1 to 40 solution of carbolic acid and allowed to remain in this solution a few minutes, the

fore skin and glans penis should be carefully washed with a solution of 1 to 1,000 bichloride of mercury. The urethra should then be washed out with a saturated solution of boric acid.

*Introduction of the Cystoscope.*—If the urethra is large and the introduction of a catheter has been easy, the cystoscope may be lubricated with glycerin, to permit of its easy passage. If, on the other hand, the passage of the catheter has been difficult, carbolized oil should be used. The introduction should always be done with the greatest gentleness, so as not to cause any bleeding. Before introducing the instrument, be sure to see that the lamp gives sufficient light. The instrument is then introduced into the bladder as though it were an ordinary sound. Often the instrument is a little soiled with blood or urethral secretions. It is therefore a wise precaution to irrigate a moment before turning on the light. In some cases the desire to urinate becomes so pressing that the instrument must be withdrawn. The withdrawal of some of the fluid will usually relieve the tenesmus sufficiently to allow the examination to be continued.

The stumbling-block which confronts the beginner most often is that the light suddenly disappears. This is caused by (1) the lamp burning out, or an interruption of the electric circuit; (2) by the lamp coming in direct contact with the vesical wall; (3) by the prism being occluded by a large tumor; (4) by the coagulation of blood on the lamp; (5) by the lamp becoming overheated and causing a burn on the bladder wall. This danger has been largely overcome by the cold lamps recently perfected.

When the beak of the instrument has been placed in the middle of the bladder, the lamp is then lit—the clear, luminous field of vision of an orange-yellow color can be seen. The beak of the instrument being held up horizontally, as indicated by the little round knob at the end of the cystoscope, the instrument is gently pulled toward the operator until a dark red border appears on the inferior part of the field of vision crossing the clearer border above. This crossing indicates that the beak of the instrument is very near the neck of the bladder—and another considerable movement will obstruct the vision, as the prism will be covered by the mucous membrane of the urethra. This darker line crossing the field of vision can be seen above, or below—to the right or to the left—but it always appears at right angles to the beak of the instrument. When we have ascertained the situation of the neck of the bladder, we proceed to the examination of the lower surface of the bladder—the beak of the instrument is rotated until it faces below, describing an arc of 180 degrees. We now look for the trigonum, which often has a color less rosy and paler than the rest of the mucous membrane of the bladder. Above the trigonum can be seen, in some cases, a light, luminous transverse line, which represents the inter-urethral muscle. It is in this position of the cystoscope, with the beak rotated below, that one tries to see the opening of the ureters. To accomplish this purpose, move the beak of the instrument toward the hip of the patient on the side you wish to explore; draw the instrument toward you, until you see the lighter color of the muscous membrane of the trigonum. If, in some cases, one cannot succeed in finding the ureter, then look for the other ureter, to see if some point cannot be discovered to help us find the first one. Sometimes one sees a drop of urine exuding, which indicates the ureteral opening. This opening generally appears as a small slit of a rosy color. After one has explored the neck of the bladder and the base, the beak of the instrument is rotated above and the upper wall of the bladder is then explored. By rotating the beak of the instrument, by lowering it, or by raising or moving it from side to side, all parts of the bladder can be seen with the No. 1 cystoscope of Nitze, with the exception only of a small portion of the posterior wall, which can be seen by the No. 3 cystoscope of Nitze.

*The Interpretation of the Cystoscope Images.*—We have seen (1) that it is necessary to learn how to insert the instrument; (2) how to manipulate the instrument in the bladder; but this is not enough, because we must learn (3) how to interpret the images we see.

Cystoscopic images are reversed, as stated by most of the writers on this subject However, this reversion is found only in the vertical plane. The objects that we see on the right and on the left, are really in these positions. .

When the cystoscope is placed horizontally and parallel to the object that one wishes to see, the image represents the object in a vertical situation, and the extremity the nearest to the observer is seen above. Thus it can be seen that the object, which is really in a horizontal position, appears to us in the vertical position, and that the part nearest the observer appears to be at the top.

If we again look at the object in the same situation, but with the cystoscope elevated to 45°, we shall again see the object completely reversed and in the horizontal position.

Thus it can be seen that the apparent position of objects varies according to the degree of inclination of the lens of the cystoscope. From this it can well be understood that in order to estimate the form of an object seen by the cystoscope it is necessary to place the cystoscope in different positions, and under varying angles of incidence, instead of being contented with the first glimpse of the object. The object appears in its normal size when it is situated three centimeters from the prism of the cystoscope of Nitze. When the prism is drawn away from the object, the object appears smaller; the nearer the prism approaches the object, so much the larger does it seem.

There has been a great deal of controversy in regard to the cases in which it is advisable to use the cystoscope. Some authorities in this country and in France neglect almost completely this mode of exploration.

The cystoscope should never be used until we have acquired accurate knowledge of the length and caliber of the urethra, and tested the capacity of the bladder.

*Diseases of the Bladder.*—It is in diseases of the bladder that the cystoscope is most useful to us. However, we must not depend on any one means of exploration for our diagnosis. We must take a careful history of the case. An accurate chemical examination of the urine should always be made. All the parts should be carefully explored. A rectal examination should always first be made, and the condition of the prostate and seminal vesicles carefully noted.

Dr. Eugene Fuller of New York deserves the credit of bringing the attention of the medical profession of this country to the importance of never failing before urethral instrumentation to make a rectal examination and determine the condition of the bladder neck. Too much attention cannot be laid on the importance of never failing to make a thorough palpation of all parts, instead of relying on any one means of exploration like cystoscopy, important as it is.

In many cases the analysis of symptoms, and the combined palpation—rectal and hypogastric—help to show us the consistence, size, and probable

nature of a tumor of the bladder. However, the cystoscope is the most valuable aid to diagnosis. It shows us whether the tumor is single or multiple and where it is located. Often when the symptoms remain latent for a long time, the cystoscope alone shows the presence of a tumor. It is only by making the most precise diagnosis possible, that we can determine the best means to employ for treatment.

Where it is evident that operative interference is useless, the cystoscope should not be employed. When the tumors are very large, cystoscopy is contraindicated, as it simply serves the purpose of causing bleeding.

The exact size and form of the tumor should be noted. When the tumor is large, it is only by a series of views that we can determine its exact size. The connection of the tumor with the bladder wall is very important to note, *e. g.* whether it is pedunculated, sessile, or infiltrated. The small villous tumors, finely pedunculated, are easy to see; their filaments flutter in the fluid in the bladder and show very well all the details of their structure.

It is unfortunate that there is no accurate concordance between the histological nature of the neoplasm and its macroscopical form. Indeed, even when the surgeon has the tumor in plain view during an operation, an accurate diagnosis cannot be made until a microscopical section has been examined. However, when a villous tumor is finely pedunculated the chances are that it is not malignant. When the villosities jut out in a solid mass from a solid base, epithelioma should be thoughtof. Nearly all cases of a villous growth of the bladder if left long enough will become malignant. In a case of a villous growth of the bladder, the history of which was followed for twenty-five years by Prof. E. S. Wood and Dr. Ogden, in Boston, the growth in the end became malignant.

In diseases of the prostate gland the cystoscope is sometimes an aid to diagnosis. It will frequently show us the extent to which the lobes bulge into the bladder. In hypertrophy of the median lobe, the cystoscope alone can tell us at what point the lobe is pedunculated, or whether the conditions are more or less favorable for a partial prostatectomy. In cancer of the prostate the cystoscope is not indicated, as it simply serves the purpose of causing a hemorrhage.

In cases of foreign bodies, the cystoscope can be used when the diagnosis is doubtful. In vesical calculi, the metal explorer usually makes the diagnosis without the use of the cystoscope; but we have found calculi in the bladder in two cases in which no symptoms pointed to their presence. After the operation of lithotomy, the cystoscope can be used to see if all the particles of stone have been removed.

In nearly all cases of acute cystitis the cystoscope is contraindicated. In tuberculous cystitis Fuller says that instruments should not be inserted into the bladder. In such instances the pain on instrumentation is very marked and the intolerance of the bladder very great. Nevertheless, the cystoscope alone can tell us the extent of the parts involved.

The diagnosis of vesical tuberculosis is not always easy to make. The bacilli are very difficult to find, and often cannot be found even after repeated examinations covering a long period of time. Cystoscopy, when it can be employed, removes the doubt, but the resulting augmentation of painful symptoms caused by this procedure will sometimes cause the doctor to lose his patient, and be cordially remembered for some time.

Ulcerations are very rare, but the cystoscope alone reveals their presence.

In this paper we have attempted to give only a general outline of the various conditions in which the cystoscope is of assistance in determining the diagnosis in a given case. There is no reason why the cystoscope should not become a routine part of our examination when at all indicated in dispensary work. Only in this way can we gain sufficient practice to use it with the best results.

---

## A CASE OF PARAFFIN INJECTION INTO THE NOSE FOLLOWED IMMEDIATELY BY BLINDNESS FROM EMBOLISM OF THE CENTRAL ARTERY OF THE RETINA.*

By LEE MAIDMENT HURD, M.D., and WARD A. HOLDEN, M.D., NEW YORK.

This case is reported because it adds another to the list of unfortunate results following paraffin injections, and also because it permitted the study of the retinal changes almost from the time of formation of a true embolism of the central artery. The latter point is of interest because we now are learning that plugging of the retinal arteries, formerly always called embolism, is in reality chiefly due to endarteritis obliterans.

*The Operation.*—The patient, V.M., aged thirty-two years, an Italian by birth, came to Dr. Hurd to be relieved of the deformity of a saddle-shaped nose. At the age of sixteen, he said, a "pimple" developed within his nose, and when incised by a physician pus escaped. In the course of three weeks the nose sunk in, and has since remained in the same condition. A loss of part of the cartilaginous septum seemed to be the cause of the deformity. He admitted having had gonorrhœa several times, but denied having had syphilis. A later careful physical examination revealed no affections of the heart, lungs, liver, spleen, or kidneys, nor any evidence of arteriosclerosis in the retinas or in the body generally.

On October 5, 1902, after the use of a 4 per cent. cocaine solution, enough paraffin was injected into the depressed soft parts below the nasal bones to restore the nose to its proper shape. Except for some swelling and redness, the result was satisfactory.

On November 17 the patient requested that a slight irregularity about an inch from the tip of the nose on the right side be corrected by a second injection. This was done without any bad result.

On April 24, 1903, he returned again and requested that a little more paraffin be introduced near the site of the second injection. A mixture of paraffin (130° F.) and ordinary white vaselin, having together a melting point of 110° F., of semisolid consistency, was injected without the previous use of cocaine, the needle being introduced first at the tip of the nose and pushed upward an inch, and then introduced at the root of the nose and pushed down to a spot just above the former injection. At this time the patient was seen to rub his right eye, and in reply to a question, he said that he could not see with it. A little later ecchymoses appeared about the tip of the nose, indicating that a vein had been punctured.

*Ocular Examination.*—Twenty-five minutes after

*The patient was presented before the Laryngological Section of the New York Academy of Medicine, May 27, 1903.

the injection the eyes were examined by Dr. Holden. The pupil of the right eye was large and did not respond to light. The patient had a subjective sensation of objects swimming about in the entire field of vision, but objectively he was unable to distinguish between light and dark. The media were clear, the retina was not hazy, and the retinal veins were normal. The main inferior branch of the central artery of the retina and its divisions, however, were empty and collapsed, being recognizable only by the faint white outlines of their lateral walls. The main superior branch contained some blood, but when gentle pressure was made upon the eyeball, the blood column here broke up and the blood flowed backward into the central artery.

It is now believed that the blood column must show these interruptions before a diagnosis of embolism can be made, for the circulation is not entirely wanting, at least in the beginning, in the cases of blindness due to narrowing of the lumen of the vessels from thickening of their walls.

*Treatment.*—When the central artery is blocked by an embolus and there is blindness in the entire field, the indication is to force the embolus forward into one of the branches of the central artery, whereby vision is restored in a part of the field. To accomplish this the action of the heart is stimulated, the peripheral vessels are dilated, and the eyeball is pressed back into the orbit until the ocular vessels are empty, and then suddenly released in the hope of drawing the embolus on by suction.

In our case digitalis was administered at once, and then inhalations of nitrite of amyl were given, after which the ball was pressed back into the orbit to the point of tolerance, and then suddenly released. This message after the inhalations was repeated several times in the course of two hours. Some hours later glonoin was substituted for the digitalis, and after inhalations of nitrite of amyl several more efforts were made to dislodge the embolus. The same course was pursued the following day also, but no vision was obtained.

Two hours after the patient was first seen, the white disc had become slightly blurred at its margins and the retina about the larger vessels was hazy. The repeated massage had forced the blood out of both arteries and veins, so that the retina was entirely bloodless. Three hours later the blood had returned to the veins, and the superior artery was partly filled, but pressure at once emptied all these vessels near the disc, while in the periphery their blood columns persisted, although in many vessels it was broken. The retina near the large vessels and in the elliptical area included within the large vessels was then very œdematous, and the usual red spot at the macula was clearly marked. There was no improvement in vision later.

Bad results following the injection of paraffin have often been hinted at, but few cases have been definitely reported. In the *Clinique Ophtalmologique*, 1902, p. 116, it is mentioned that Pfannenstiel and Hölban have seen cases of pulmonary embolism, and that embolism is more likely to occur when liquid paraffin is used. Elsewhere in the same volume Kümmel remarks in a discussion that fatal cases of pulmonary embolism have been observed. Pfannenstiel's case (*Centralblatt für Gynäcologie*, 1901, No. 2, p. 33) was one in which he injected 30 c.c. of paraffin, 45°C., according to Gersuny's method, to relieve incontinence of urine in a woman whose urethra had been extirpated for carcinoma. After leaving the hospital the patient was attacked with symptoms indicating embolism of the lungs and brain. Eventually she recovered.

The only case of blindness after injection that we have been able to discover in the literature is the frequently quoted case that Leiser reported. (*Vereinsbeilage der deutschen medicinischen Wochenschrift*, April 3, 1902, p. 110.) Briefly it was as follows: After the third injection of paraffin into the nose the patient collapsed, but recovered after the injection of ether and the performance of artificial respiration, although he continued to vomit for hours. After recovering consciousness the patient found that he was entirely blind in his left eye.

January 25, the following day, Dr. Rischmüller found the left upper lid œdematous, the eyeball injected, the pupil not responsive, and the aqueous humor cloudy. The ophthalmoscopic examination was difficult, but the disc was found to be unchanged, and the surrounding retina œdematous. The motility of the eye was limited downward and outward, and the tension was—1. January 26: The hyperæmia, and the cloudiness of the aqueous humor increased. January 27: Œdema of lids, lacrymation, and hemorrhages into the iris. January 28: Interior of the eye clearer, disc red, veins well filled. January 29: External conditions improved, no hemorrhages in the retina. February 2: Beginning pallor of disc.

Leiser believed that there had been thrombosis of the ophthalmic vein into which runs the vena dorsalis nasi that might have been punctured in the operation. No note is made, unfortunately, of the condition of the retinal arteries. Thrombosis of the ophthalmic vein far back, or of the cavernous sinus into which it enters, might have accounted for the symptoms observed, but it is remarkable that a foreign body entering a small vein should pass centripetally toward the heart and be caught in a vein of much larger caliber.

The pathological conditions are no clearer in our own case of embolism of the central artery of the retina, since a foreign body large enough to block the large central artery and resist all efforts to force it along into a smaller branch, can hardly be supposed, after entering a vein, to pass through the capillaries of the lungs and back to the left side of the heart, and thence into the general arterial circulation. Dr. Evan Evans, who kindly made a physical examination of the patient, suggested the possibility of there being a persistent foramen ovale between the two auricles, through which foreign bodies entering the veins might pass directly from the right to the left auricle and, avoiding the pulmonary circulation, give rise to a crossed or paradoxical embolism, so-called, somewhere in the general arterial circulation. Since communications of considerable size between the auricles are not infrequently found at autopsies, this explanation seems plausible.

The obvious lessons taught by these cases is that loss of vision, and even of life, may follow the injection of paraffin into a vein. This danger could be partly avoided, doubtless, by performing aspiration after the introduction of the needle, and if there was no evidence of penetration of a vein, injecting the paraffin through the needle without moving it. There would remain, however, the possibility that the needle had passed entirely through and beyond a vein, and then the paraffin when injected under high pressure might, in its ramifications, pass backward along the course of the needle and thus gain entrance to the vein.

At all events, the operation is not so lacking in danger as the frequency with which it is done to improve the appearance or increase the comfort of the patient would seem to indicate.

## SOME PRACTICAL REMARKS ON THE MANAGEMENT OF BREECH PRESENTATIONS.

By JOSEPH KUCHER, M.D.,
NEW YORK.

Practitioners usually dread cases of breech presentation on account of the dangers to the child. The dangers lie, however, not so much in the presentation as in the improper management. Too early or too hasty interference by the attending physician is usually the cause of all the troubles incident to breech presentations. As even a short labor lasts too long for the sufferer, the attending physician is always more or less urgently asked to do something to shorten the time of suffering. If a foot or a knee is within reach (as it is in incomplete breech presentations), the attending physician is easily tempted to pull on the extremity, in the belief that by doing so, he can shorten the time of suffering without doing any harm. In other cases the attending physician interferes too soon because he sees danger to the child life when there is no danger. Passage of the meconium or prolapse of the cord has not the same significance as in head presentations, and offers, therefore, no indications for interference. Such interference always endangers more or less the life of the child, and besides it is not necessary.

In the great majority of cases there is no danger to the child before the breech appears at the vulva. At this time the head enters with its greatest circumference the brim of the pelvis and fills the space so completely that the circulation in the cord is soon suppressed, and the child must be delivered in a short time, which is easily done if the labor has taken its natural course, without any outside interference. In such a case the arms of the child have remained in their natural position on the chest, the lower uterine segment had been gradually and completely dilated and offers very little resistance to the passage of the head. All this is changed if premature tractions have been made on the lower extremity of the child. The arms have been pushed up above the head, and the body of the child, as it is very compressible, has been forced through the uterine orifice, before the lower uterine segment has been sufficiently dilated for the passage of the head. These two complications make us lose much valuable time at the last stage when quick delivery is very important. As the arms are high up, it is hard to reach the elbow and hard to bring the arm down, after this the greatest circumference of the head offers the greatest difficulty in extraction if the lower uterine segment is not sufficiently dilated. It is much easier to overcome a considerable disproportion between the head and the pelvis than to extract the head when it is still firmly retained by the lower uterine segment. In the former case pressure by the hand of an assistant from above is of great help, while in the latter case it is of very little use. The resistance encountered in such cases is usually attributed to a contracted pelvis, but in ninety-nine out of one hundred cases it is the lower uterine segment that offers the resistance.

In complete breech-presentations (that is, when no lower extremity is presenting) there is no danger of too early interference by the attending physician. But there arises, especially in primiparæ, not rarely another difficulty that is not met with in incomplete breech presentations. The labor may have progressed quite satisfactorily up to the last stage, and then the pains may stop or become so lagging that for hours the labor makes no progress. It becomes necessary to interfere, as a too long delay at this stage would be dangerous to the mother and to the child. But the difficulty now is, how to do it before the breech is near the vulva. As such a contingency may arise in every case of breech presentation, it has been suggested to bring a foot down at the beginning of labor, but this cannot be done when we find the breech already engaged in the pelvis. Divers devices have been proposed and tried in such cases. When the child is dead, the simplest way to extract the child is with the blunt hook in the groin. Although I have extracted in this way several times large children without the least injury. I never dared to use the hook on a living child, and was the less tempted to do so, as I found the forceps very satisfactory. Some precautions are necessary in using the forceps. It should not be applied before the breech is down in the pelvis, the handles should not be pressed too firmly together lest the blades injure the soft parts. By inserting a folded towel between the handle of the forceps, too hard pressure by the tips of the blades on the soft parts of the child can easily be avoided. The tractions, moreover, should be made slowly and only during a pain. In a case that I saw recently with Dr. H. Kudlich, I tried for the first time the short forceps, but found it so unsatisfactory that I had to exchange it for the long one, with which the extraction was very easy.

Lacerations of the perineum can be more easily prevented in breech presentations than in head presentations, though the reverse usually happens. Though by the passage of the trunk the perineum has been considerably stretched and prepared for the passage of the head, still the extraction of the after-following head must be made slowly and properly. By an assistant or by one hand of the accoucheur, the body of the child should be lifted toward the abdomen of the mother, and by the other hand the perineum should be supported. When once the mouth of the child is outside the vulva, there is no danger of the child filling his lungs with mucus, even if it begins to make premature respirations, and we can, therefore, take our time in letting the greatest circumference of the head pass slowly through the vulva, and so avoid laceration of the perineum.

**The Indications for Operation on the Thyroid Gland in Graves' Disease.**—Leonard Woolsey Bacon summarizes his paper in part as follows: The two doctrines as to the pathogenesis of this disease are that of thyroid intoxication and that of primary affection of the sympathetic nerves and ganglia. The intoxication may be considered as that from mere hypersecretion, and that from perverted secretion. In cases of the type of "thyroid intoxication by excess of secretion," operation on the thyroid is indicated in all cases of more than a few months' duration in which the gravity of the symptoms warrants the exposure of the patient to an operation having a general mortality of about 7 per cent., provided that the cases have not been decidedly benefited by reasonable non-surgical treatment, or by surgical means addressed to other diseased organs. In cases of the type of "thyroid intoxication by perversion of secretion," the indication for operation on the thyroid is much less decided, and in many cases, especially those in which there are concomitant symptoms of myxœdema, operation on the thyroid gland is contraindicated. In this class of cases the risk is greater and the chances of betterment by operation are less. In the two preceding classes of cases it is reasonable to be guided as to operation by the effect on the patient of the tentative administration of thyroid extract. Those cases in which the symptoms are aggravated by the thyroid extract will be the more likely to be helped by thyroid operation. The indications for operation are less strong in cases of Graves' disease of the "sympathetic type,"

so-called "sympathectomy," being probably the preferable operation if surgical measures are to be employed at all. In cases of goiter secondarily exophthalmic the indication for thyroid operation is strong. Further indications for thyroid operation in Graves' disease are the general indications for surgical intervention in other parts of the body, thyroid abscess, pressure symptoms, malignant disease, etc. The more typical and regular the case of Graves' disease, the more likely it is to be benefited by operation on the thyroid gland, while, the more widely the symptoms differ from those known to be due to simple hyperactivity of the thyroid, the more ready should we be to turn to other methods of combating the disease. —*Yale Medical Journal.*

**The Paroxysms of Whooping-cough Treated by Pulling the Lower Jaw Downward and Forward (Naegeli).**—Jacob Sobel gives the results of his own experience with this method: Pulling the lower jaw downward and forward controls the paroxysms of whooping-cough in most instances and most of the time. The method is usually more successful in older children than in younger ones and infants. In cases without a whoop the expiratory spasm with its asphyxia is generally overcome, and in those with a whoop the latter is prevented. It is as successful as any single drug, or even more so. Mothers should be instructed in its use, so that attacks, especially at night, might be arrested. The manipulation is harmless and painless. Its only contraindication is the presence of food in the mouth or œsophagus. Patients thus treated are less likely to suffer from complications and sequelæ than those treated only medicinally. It is advisable to try this method in other spasmodic coughs and laryngeal spasms. The patient should also be afforded every possible hygienic advantage, he should be supported and sustained and be well looked after as to his gastro-intestinal tract and nerve centers. The method is especially indicated in those cases complicated with diffuse bronchitis, bronchopneumonia, convulsions, epistaxis, etc., and in those, who by age, rachitis, scrofula, or general debility are predisposed to serious complications and sequelæ.—*Archives of Pediatrics.*

**On Certain Bodily Conditions Resisting Phthisis.**—Arthur Ransome refers to the well-known enumeration of Walshe of morbid conditions opposed to phthisis, viz., anthracosis, rickets, gout, cancer, diathetic skin diseases, as pemphigus, emphysema, nodular pulmonary apoplexy and active organic cardiac disease, including aneurysm and angina. He assents, in a general way, to the truth of this contention, but believes that the experience of recent years has led to a more careful differentiation of the clinical conditions comprised in the above list that may lead to a resistance against tuberculous invasion. Ransome inquires if there may not be some bodily condition common to all these disorders; a condition which presents a hindrance to the entrance or growth of the tubercle bacillus? He believes that such a common bodily state *does* exist and applies to it, for want of a more definite term, the name "venosity"—as Rokitansky first suggested. It probably means a plethoric condition of the capillary system of blood vessels, with imperfect reaction of the blood; in other words, an excess of red blood-corpuscles, increased alkalinity of the blood, and increase of carbonic acid. It is difficult to say which of these conditions is chiefly antagonistic to tuberculosis, but, perhaps, all three are so.—*Medical Chronicle.*

**A Consideration of the Liver as a Factor in the Cause, Prevention, and Treatment of Disease.**—Robert S. Lamb says that experience teaches us that many diseases are the result of long abuse of the digestive system and accumulation of waste products of malnutrition and malassimilation which the overworked excretory organs cannot eliminate; these are predisposing factors in the acute infectious diseases. The liver in its normal condition will prevent the passage into the blood of certain deleterious substances, will form products that antagonize some otherwise poisonous substances, as caffeine, nicotine, indol and skatol, and attenuate or render innocuous the bacteria and their toxins; it will allow the necessary amount of glycogen for nourishment of the tissues to pass into the blood, and will excrete some injurious products, and aid in the excretion of others. To restore equilibrium we must regulate the diet, give the digestive organs rest, and prescribe only small quantities of easily digested food, in order that no undigested, putrefying material be absorbed and carried to the liver. Exercise, deep breathing, and massage are all of the greatest value. Organotherapy is beginning to be useful in treating diseases of the liver, and diseases caused by the products of the liver.—*Washington Medical Annals.*

**Furunculosis: a Survey and an Application.**—A. C. Miller says that as soon as a boil has appeared, the most scrupulous care should be bestowed upon it, with the view of limiting its infectivity. Unna's mercurial plaster, or its equivalent, ought in the first instance to be applied in the the hope of promoting absorption. In the event of this object being defeated, maturation should be promoted by means of an antiseptic dressing, and the discharge should be very carefully guarded from coming into contact with the surrounding skin. Should the furuncle assume the dimensions of a carbuncle, this ought not to be incised, but it will be advisable to enlarge or connect the fenestræ in the skin in order to allow freer egress to the discharge and slough. The local condition being the paramount one in the class of cases now under consideration, it is necessary to regard the constitutional element only in the sense of maintaining the general tone. The author has always had good results from exhibiting morphia to control pain and favor sleep. Iron and arsenic are invaluable hæmatonics, while wholesome—not too generous—feeding, with, in depressed anæmic cases, the administration of suitable stimulants in careful quantity, completes the therapeutic repertory.—*Edinburgh Medical Journal.*

**A New Application of Light in the Treatment of Lupus Erythematosus.**—Norman Walker states that a student having called his attention to the fact that his nose, which was the seat of the disease, invariably improved after exposure to the glare from the water when fishing in the Highlands, he resolved to try the effect of light only on lupus cases, without pressure or aiming at the blistering effects which the Finsen methods have in view. His patients were seated about a foot away from the lens, and were exposed to the rays for from twenty minutes to half an hour daily, or on alternate days. Six or eight exposures, roughly three and a half to four hours, were usually required before any change was noted, but when improvement had once begun it was usually rapid. In some of the cases the results have been brilliantly successful, and all have shown some improvement. Large areas of the disease have disappeared in some cases more thoroughly than under any other method with which the author is familiar. In the early cases he, of course, used no other treatment, but latterly, having determined the value of the method, he has been using in addition applications of adrenalin chloride, 1 to 4000, which seems to aid in the cure.—*Scottish Medical and Surgical Journal.*

**Boiling as a Method of Sterilizing Catheters.**—C. B. Nancrede and W. B. Hutchings conclude from their experimentation that caloric can be successfully employed for all varieties of catheters with the exception of the soft French instrument, provided all air is expelled from the interior. (2) That this essential having been secured, although in the great majority of cases five minutes' immersion in water which is actually boiling will suffice, ten minutes of actual ebullition should be employed, especially for the smaller calibered instruments: and (3) that a previous cleansing with warm soapsuds is desirable although not essential, reducing as it does the time of exposure requisite to sterilize the instruments.—*Journal of the Michigan State Medical Association.*

## THE DISINFECTANT VALUE OF SULPHUROUS ACID.

IN the *Revue d'Hygiène* for May 20, 1903, Drs. Calmette and Rolants discuss this question. They had previously found that the germs of plague, cholera, and typhoid fever were easily destroyed by exposure for two hours to air containing 8 per cent. *ad minimum* of sulphurous gas (this term denoting the vapors resulting from the combustion of sulphur in air). But the discordant opinions arrived at by different investigators of late years determined them to undertake a new line of studies with a view of harmonizing the discrepancies, and of elucidating the reason of the wide divergence of opinion as to the efficiency of this gas. They used the gas in three forms. The vapor of sulphur burned in air, the vapor of sulphur burned in Clayton's apparatus, and the vapor obtained by volatilizing the liquefied sulphurous acid gas furnished in siphons. The distance to which the gas penetrated substances such as mattresses and different fabrics was also determined by special methods. To clear the ground it may be stated that the gas derived from the siphons (pure sulphurous anhydride, $SO_2$), proved entirely devoid of bactericidal properties, even when used in the enormous proportion of 22 per cent., with a six hours' exposure and a penetration of 28 cm. The diffusibility of the gas is small and it tends to collect at the floor level. When the liquid siphon contents is volatilized, there is no cloud, the liquid evaporating into the air transparently. But when sulphur is burned in the air, or in the Clayton furnace, a greater or less amount of dense, opaque, white fumes is given off. These consist of sulphuric anhydride ($SO_3$). The authors were able to show that it is precisely this substance (absent from the vapor derived from the siphons) which confers upon the gas obtained by combusion of sulphur in the air or in Clayton's furnace its extreme toxicity for animals and non-sporing microbes. It then becomes a matter of great interest and practical importance to determine the conditions under which it is produced in quantity sufficient to give the sulphurous gas antiseptic properties which the pure sulphurous acid gas does not possess, or possesses in too feeble a degree to permit of dependence being placed upon it as a disinfectant. Calmette and Rolants found the proportion of sulphuric anhydride in sulphurous gas obtained by burning sulphur in air to be only 0.1 milligram per liter, while that obtained by the combustion of sulphur in Clayton's furnace contained from 4.2 to 6.46 milligrams per liter. The gas obtained from Clayton's furnace (and that derived from the volatilization of the contents of the siphons) does not injure fabrics or other articles such as books, gilding, oil paintings, and cereals. But to avoid condensation of moisture upon them (and consequent formation of sulphuric acid) they should be covered with paper. When, however, one burns sulphur in the air, manifest injuries to the articles named, result. This is due to condensation of moisture from the air, explained by the authors as due to its rapid cooling consecutive to the heating by the combustion, which may raise the temperature from 12° to 39°. Thence results an abundant formation of sulphuric acid, which attacks the metals, and rapidly decolorizes the draperies. About 40 grams of sulphur produces the proper amount of gas for disinfecting an ordinary room. The maximum concentration obtained by Calmette and Rolants in the air of the room was 4.6 per cent., and the gas penetrated fabrics to the depth of 21 cm. The following results were obtained with cultures exposed to the action of the gas, the *minus* sign indicating sterile; the *plus* sign, not sterilized:

| | Air | Clayton Conc. $\frac{8}{10}$ Per Cent. |
|---|---|---|
| Streptococcus, dry cultures mixed with blood | — | — |
| Bacillus typhoides, dry, without blood | — | — |
| Bacillus typhoides, dry, with serum | + | — |
| Bacillus diphtheriæ culture, dry, without serum | + | — |
| Bacillus diphtheriæ culture, dry, with serum | + | + |
| Bacillus of charbon, sporing, dry, without and with serum | + | + |
| Bacillus tuberculosis | + | + |

A concentration of 12 per cent. sterilized, in addition, the fifth culture in the table.

The authors arrived at the following conclusions:

Sulphurous gas produced by the combustion of sulphur in air or in Clayton's furnace possesses a disinfectant power with regard to certain pathogenic microbes which are relatively easy of destruction, such as the streptococcus of erysipelas, and the bacillus of typhoid fever, even when these microbes are placed under the best conditions of resistance, that is when they are protected by an envelope of dry albumin. But one should not count upon its absolute efficiency in attacking resistant pathogenic organisms, such as bacillus diphtheriæ, bacillus tuberculosis, and, above all, the sporing microbes. The disinfectant properties of sulphurous gas are due to the presence in it of sulphuric anhydride, which is always present in greater or less amount. The largest proportion, and consequently the best results, attained by the burning sulphur in the Clayton furnace, are due to the fact that the gas thus obtained is richer in sulphuric anhydride than that obtained by combustion of sulphur in air. The sulphurous acid gas derived from the volatilization of the liquefied gas in siphons possesses no disinfectant value even in a strength of 22 per cent.; and it should consequently be entirely abandoned as a disinfectant for localities infected with pathogenic microorganisms. To obtain efficient disinfection by sulphurous gas, where pathogenic microorganisms are in question, it is necessary to be certain that the air is charged with, for at least two hours, 8 per cent. of the gas *ad minimum*. Every

time one attempts disinfection by sulphurous gas it is indispensable that he determine by simple yet rigorous methods of control the mean concentration of the gas, the distance of penetration across permeable objects capable of harboring pathogenic microorganisms, and the bactericidal efficacy of the gas with regard to the particular microorganisms which it is desired to destroy; and no disinfection should be carried out without this triple control. When employed under all the conditions outlined above (of which the most important are, a concentration of 8 per cent. *ad minimum*, an exposure of at least two hours, and a sufficient agitation of the air to ensure penetration through the whole permeable mass capable of harboring pathogenic microorganisms or animals, especially insects), sulphurous gas can be used as a disinfectant; and it should still be retained, but it should not be substituted for formalin, which, it would seem, ought to be the disinfectant of election for apartments. But sulphurous gas deserves to be employed wherever large spaces (such as ships, railroad coaches, and above all, granaries) are to be disinfected. It finds its especial field where one wishes to destroy both germs easy of destruction (*e. g.* the germs of plague, cholera, typhoid fever, and erysipelas), and insects and rats, on which formalin does not exercise a noxious influence. As Vallin has said: "It is not necessary, by reason of certain exceptions which we do not deny, to depreciate unduly the value of sulphurous acid, which is, in truth, one of the most efficacious, the most economical, and the most easily applied agents that we possess."

## ZOMOTHERAPY IN TUBERCULOSIS.

In the June issue of the *American Journal of the Medical Sciences*, Dr. Lawrason Brown of Saranac Lake discusses the merits or otherwise of a diet of raw meat in the treatment of tuberculosis. Richet and Herincourt, the well-known French scientists, were the first to experiment with raw meat as food for consumptives. The experiments were carried on with dogs, and as a result they concluded that cooked meat in any quantity is inefficacious, that meat deprived of its serum is moderately efficacious, and that muscle serum is as efficacious as raw meat. They also found that raw meat acted prophylactically. Several other scientists, nearly all of whom were Frenchmen, followed the lead of Richet and Herincourt. Among others Chantemesse, who was at first sceptical as to the great nutritive qualities of raw meat, became a convert to a belief in its efficacy, owing to the result of experiments on dogs undertaken by himself. Duhoureau, Petit-Clerc, Sarge, Josias, and Roux have all expressed themselves as adherents to the view that raw meat is the most beneficial diet for consumptives. Struck in the same manner as Fränkel was by the meagerness of the experimental work—Chantemesse, Salmon, and Fränkel being, apparently, the only observers to repeat Richet's work. Fränkel obtained opposite results, Salmon's results were inconclusive, while Chantemesse, from experimenting on two dogs, upholds Richet. Dr. Brown, at the instance of Dr. Trudeau, carried out some experiments similar to those of Richet.

Five dogs were inoculated in the external popliteal vein with 2.5 c.c. of a translucent emulsion of tubercle bacilli. Two of these animals were chosen as controls and fed on a mixed diet, the other three being given nothing but raw meat. At the end of the experiments the average life in the controls was 34½ days; and in dogs fed on raw meat, it was 31½ days. The next experiments were undertaken on six dogs, all injected with an attenuated tubercle bacilli. Four were fed on raw meat, and given at the same time some fat and occasionally a little bread and dog biscuit, while the others were fed on general diet. The result was that the test-dogs lived on an average 110 days after inoculation, and the two controls on an average 308 days.

From these experiments, and from observations made in the dieting of consumptives, the author thinks the following conclusions may be drawn: (1) That raw meat has no perceptible effect on the duration of experimental tuberculosis in dogs if the bacilli are virulent, and a sufficient number injected intravenously. (2) That raw meat has no effect on the prolongation of the duration of experimental tuberculosis in dogs, even if the bacilli are attenuated, provided a reasonable quantity be injected intravenously. (3) That under the same conditions dogs fed on a mixed diet with no raw meat, live a much longer time.

Regarding the use of meat in pulmonary tuberculosis, it may be said: (1) That meat is highly essential in the dietetic treatment. (2) That much meat, with a judicious admixture of carbohydrates, fats, etc., is essential to the treatment. (3) That rare meat is better than meat well cooked. (4) That meat-juice is of great value in suralimentation, as myosin albumin is easily digested by most patients—even the dyspeptic, and it affords a "maximum of nutrient for a minimum of effort." (5) That meat-juice can be taken when patients can take no other form of meat, *i. e.* when there exists a marked repugnance to all solids. (6) That the juice from raw meat seems slightly, if at all, more beneficial than the juice from meat slightly browned. (7) That the disadvantages of preparing and preserving raw meat-juice more than offsets its advantages. (8) That meat-juice is of value, as it can be administered in the form of jellies, ices, etc.

The prevalent opinion, then, of Richet's method would seem to be that it is only a better means of offering nourishment and of enabling a larger quantity of food to be given.

## RED-LIGHT TREATMENT OF SMALLPOX.

The *British Medical Journal*, June 6, is almost wholly taken up with a discussion of the light treatment of disease by distinguished men of science. The first article of the series is, perhaps, the most important, as well for its subject matter as on account of the fame of the writer. It is entitled "The Red-light Treatment of Smallpox," and is by Prof. Niels. R. Finsen.

The writer first draws attention to the fact that ten years ago he advocated red light in the treatment of smallpox, his notice having been first attracted to the matter by some old American and English reports on the injurious effect of light in smallpox. The reason Dr. Finsen gives for taking up the subject again is because he read in an American paper a short time ago that a large number of

persons had been pitted by smallpox in the course of the epidemic which has prevailed in the United States during the past four years, and also because he saw in the *Lancet* statistics showing the prevalence of and large mortality from smallpox in London during 1902. He is of the opinion that the pitting might have been avoided and the mortality might have been lessened if the red-light treatment had been followed in America and London respectively.

Dr. Finsen states that, from numerous trials, together with various simultaneous controlling experiments, it may be considered as an irrefutable fact that daylight, and especially the chemical rays, has a most injurious effect on the course of smallpox, as the suppuration of the vesicles is due to the effect of light, and that accordingly it is possible to avoid the suppuration and its consequences by protecting the patients from the action of light. Light has a most deleterious effect on smallpox, and, according to Dr. Finsen, the red-light treatment is one of the most striking results known in medicine. Even in cases of confluent smallpox, or in unvaccinated persons, the method very rarely fails, supposing, of course, that the patient comes under treatment early enough. If, however, suppuration has begun, or is on the point of beginning, the red-light treatment will not then stop it.

In the article contributed to the *British Medical Journal*, Dr. Finsen regards the matter from the standpoint of public health, indeed the main object that induced him to write was to urge upon the health authorities of Great Britain the need of reconsidering their methods of treating smallpox in the public hospitals. He holds the view that it is absolutely unwarrantable on the part of the public health authorities to treat serious cases of smallpox, in which suppuration might be expected, in hospitals where patients are exposed to daylight, while as to the private physician it must be considered a gross shortcoming if, as soon as he diagnoses smallpox, he does not make preparations to prevent the patient from being exposed to daylight. In Denmark, and in several other places, the public hospitals for infectious diseases are provided with permanent red-light wards for smallpox patients. Dr. Finsen ends his article by declaring that although irrefutable scientific evidence has been given that light is most injurious in promoting suppuration in smallpox, nevertheless if scepticism on this point still exists, he would greet with pleasure the appointment of a commission to make a thorough investigation into the matter, and that he would be happy to place himself at its disposal with all the information at his command. He further suggests that if such a commission be appointed, it should consist—in addition to smallpox experts—of dermatologists who are aquainted with the action of light on the skin.

There is no doubt but that the question is one of superlative importance, and if it can be conclusively proved that the red-light treatment of smallpox will prevent suppuration, this course should be universally followed. It is curious how some of the old-time theories as to the treatment of disease, though long scoffed at, have eventually showed themselves to be not altogether wrong. The mode of treating smallpox patients by the exclusion of light was practised by many physicians in this country and in England a great number of years ago. Pictou wrote advocating the treatment in the United States in 1832. The practice was afterward poohpoohed as having no basis of reason, and fell into desuetude. Now that the therapeutic importance of light is aserting itself, it is only in the natural order of things that the question of light and its action in smallpox should be thoroughly investigated, and the matter definitely decided.

## Carlyle and His Wife.

Froude's "Life of Carlyle," from the time it first saw the light, has evoked a storm of criticism and controversy. The biography of the celebrated Scotchman has, indeed, proved to be a bone of contention. The adherents of Carlyle have declared and still assert that Froude has grossly maligned the great man, either through malice or through possessing a too exuberant imagination. The question as to whether Mrs. Carlyle was an ill-used woman or merely an hysterical one, has been left more or less at rest for a considerable time. Now, however, the storm has again broken out with increased violence, and the literary and journalistic world of Great Britain is all agog, and even some of the medical journals are taking part in the wordy battle. The reason for this stirring of sleeping fires, is that a book has been recently published by two relations of Carlyle, containing further letters of Mrs. Carlyle, and a long introduction by Sir James Crichton-Browne. The contents of this volume purport to be a complete vindication of Carlyle and incidentally are somewhat of a vilification of Froude, or rather of the methods he used in compiling the famous philosopher's biography.

Sir James Crichton-Browne, who is the well-known British alienist, states that Mrs. Carlyle was of an extremely neurotic temperament, and that the letters in which she brings charges against her husband were merely the ordinary manifestations of such a condition. She was, moreover, addicted to some extent to the morphine habit, which, of course, is calculated to render a person irritable and suspicious. The English physician makes a strong and forcible defence of Carlyle's character, which, however, does not appear to be entirely convincing.

The *British Medical Journal*, June 13, has an article on the subject in which, while allowing that Sir James Browne makes a good case, is yet inclined to think that not all the fault lay on the wife's side, but that Carlyle was a most difficult, almost impossible, person to live with in domestic harmony and peace. The part of the article referred to reads as follows: "While we hold that Sir James Crichton-Browne has made out his case as to Mrs. Carlyle, we do not think that he has succeeded in vindicating Carlyle's character as a husband. No ingenuity in explaining away his use of the word "remorse" can wipe out the record of his unavailing contrition when he found what a tragedy he had made of her life. It would be idle to blame him; he was wrapped up in his work, and took the self-sacrifice of his wife, as he took his morning porridge, as a matter of right. Thackeray, the arch-enemy of snobs, confesses that in his heart he was himself a snob. Carlyle, less sensitively self-conscious, never seems to have suspected that he, the denouncer of shams, was himself deluded by shams, giving to poor, hopeless souls who asked for the bread of guidance the stone of a vague appeal to the veracities and silences." There is another point which

has been widely and almost shamelessly discussed by the lay press of England: the question as to whether Carlyle was physically fit for marriage. It has been hinted on many occasions and from many quarters that to his physical unfitness was due much of Mrs. Carlyle's domestic infelicity. Whether this were so or not will never be settled, and thus it is useless to debate the point. To one who has never dived very deeply into "l'affaire Carlyle," but has been simply a cursory reader of some of the literature on the subject, the unhappiness of the marriage would appear to have been chiefly, if not wholly, caused by incompatibility of temperament. There are no people more difficult to live with than those endowed with that indefinable attribute known as genius. Their mental make-up is altogether different to that of the common crowd, they do not regard most matters from the same standpoint; in a word, they inhabit a world of their own and have little sympathy with or understanding of beings of a more common clay. They are unwittingly but inordinately selfish. Now Carlyle was a genius and, in addition, a dyspeptic. Mrs. Carlyle, although not to be classed in the same category, as regards the quality of her brain, with her husband, was nevertheless a highly talented and sensitive woman of very neurotic temperament. Men of genius, especially if they are dyspeptic as well, should never marry, and when they do marry they should choose as mates, women of the fat, easy-going, lymphatic type, to whom their eccentricities and vagaries would matter nothing, and from whom their irritable or caustic words would slide like water from a duck's back.

---

### Vitality of Bacteria from the Throats of Scarlet-fever Patients.

Dr. George H. Weaver of the Memorial Institute for Infectious Diseases, Chicago, writes on the above subject in the *Journal of Medical Research* for May. From clinical observations it would appear that the specific virus of scarlatina is most tenacious of its vitality, as it lives in a dark place for a considerable time. Accordingly investigations were undertaken at the Chicago Institute to determine whether any of the bacteria found in the throat of cases of scarlatina were resistant to dessication and, if so, which ones they might be. The experiments were conducted with great care, and the result of the observations showed that streptococci are more abundant early in the disease, becoming less numerous as the disease progresses, and that the streptococci resist dying as long as the other bacteria which are usually present in the throat, and in many instances outliving all the other forms. The longest time after which streptococci could be cultivated from the dried material, *i. e.* ninety days, does not correspond to clinical observations where the scarlatinal virus is said to have produced infection after lying dormant for years. With regard to the study of pure cultures of streptococci, the most valuable observations made were as to their vitality in milk. Twenty-one cultures were tested to show this property. Of these, two were dead in sixty days and four in eighty days. The remaining ones were dead after 140 to 160 days. One culture was still alive after 200 days. It was not found that life was lost sooner when the milk was coagulated. A second series of tests was made with twenty-two cultures, using in part the same, together with additional, cultures, after they had been grown on artificial media for a longer time, and after they had passed through ten to fifteen generations on various media. Of these 11 were dead in 18 days, 6 in 54 days, 2 in 76 days, and the remaining 3 were alive after 90 days. The resistance of the bacteria would thus seem to have been reduced by prolonged cultivation. The conclusions reached were as follows: (1) Streptococci are almost always, if not constantly, present in the throat in cases of scarlatina. In early stages they are usually present in very large numbers, becoming less numerous as the disease progresses. (2) The streptococci in the throat of scarlatina patients resist dying as long as the other bacteria usually present, and they often outlive all other forms, being alive as long as ninety days after the material is collected. (3) The streptococci remain alive for a long time in milk. (4) A small amount of sugar in nutrient media increases their value for the cultivation of streptococci. (5) Streptococci from scarlatinal anginas are not different from streptococci from other sources, so far as cultural and morphologic peculiarities are concerned.

---

### Roman Catholicism and Leprosy.

The connection between Roman Catholicism and leprosy, to the uninitiated, is not very plain of perception, but Mr. Jonathan Hutchinson traces a very close relationship between this branch of Christianity and the loathsome disease. Fish is the connecting link. As Mr. Hutchinson is of the opinion that Christianity was responsible for the spread of leprosy in Europe, so, he thinks, that to the Catholic missions are due the increase of leprosy in the Far East. He argues thus: Figures show that a convert from Hinduism to Roman Catholicism incurs at once an enormously increased risk of becoming a leper. Conversion to any of the Protestant sects is the means of running some risk, because it removes the prejudice to animal food which, to some extent, is natural to the Hindu mind, but the conversion to a creed which imposes the use of fish on one or two days at least of every week increases that risk immensely. Mr. Hutchinson calculates that the risk to a Catholic convert is twentyfold that of one who remains in the Hindu faith, while in Bengal this ratio may amount to ninety-fold. He holds, too, that this preponderance of the disease amongst Catholic converts in India gives the *coup de grâce* to the belief in the contagiousness of leprosy. The Indian Jain, who is a vegetarian, escapes leprosy, the Catholic suffers fearfully. "How then," he says, "is it possible that a disease spread by infection could pick out the members of one religious communion and leave another untouched? Such preferential incidence can be explained only on the supposition that it is due to some difference in habits, and most probably in connection with food. The average incidence of leprosy in India, as a whole, is less than five per 10,000; but there are three local communities—Minicoy, Salsette Christian, and Kaligoan—in which it attains the frightful prevalence of 150, 50, and 500 per 10,000, and these are all places where the inhabitants live by fishing."

Mr. Hutchinson, contrary to general expectation, as a result of his visit to India, has not only retained his long-held beliefs concerning fish and leprosy, but actually seems to have strengthened them. He strongly asserts that the consumption of putrid or tainted fish is the cause of the leprosy which exists in India, and he has appealed to the Government to take the tax off salt, so that the natives may be able to cure the fish which they wish to use as food.

### The Fourth of July and Tetanus.

The fourth of July has passed by this year with about its usual quota of accidents. A few cases of tetanus have occurred as the result of injuries received chiefly from toy pistols. Dr. Connolly, the bacteriologist of the Newark Board of Health, raised an interesting point the other day when he declared that he had found the bacillus of tetanus in blank cartridges on sale for the July 4th celebration. If this be indeed so, a complete explanation will have been given of the numerous cases of lockjaw resulting from wounds inflicted by toy pistols. But the findings of Dr. Connolly will require further and more satisfactory evidence before they are accepted as conclusive. Dr. Park of the New York Board of Health made exhaustive investigations into the matter two years ago, and found no germs of tetanus in the blank cartridges he examined, and he remains convinced that the cause of infection, under the circumstances mentioned, is that fragments of skin, more or less covered with dirt, are driven into the wounds. This is by far the more reasonable interpretation of the origin of the tetanus which follows wounds produced by blank cartridges. The bacilli of tetanus abound in the dirt of the streets. At the time that a wound is inflicted by a toy pistol, or blank cartridge, the hands of the boy who uses the weapon are almost certain to be extensively soiled with dirt, some of which will be carried into the tissues. An instructive moral should be extracted from a study of the statistics regarding tetanus in the United States. More than half the cases of this disease are due to accidents on the fourth of July.

It is all very well to be patriotic, but when patriotism takes the form of giving pistols to children, who discharge them to their own danger and to the menace of the public at large, it is time to stop and to consider if patriotism exercised in this fashion is altogether worth while, or if is is not somewhat of a travesty of that noble sentiment.

---

### Neurasthenia.

Dr. Guthrie Rankin, in the *British Medical Journal*, May 2, discourses on that condition so often met within this country, and which may, indeed, almost be regarded as the most characteristic affection to which the native American is prone, known as neurasthenia. The name, too, was given by a New York physician, Beard, so that the malady may be really claimed as entirely American, although it is present, in a lesser degree, in most countries of the civilized world. Primitive man knows it not, it has been one of the doubtful blessings brought in by advanced civilization, and the more advanced the people, the more does this complaint increase and flourish. Its definition is by no means easy, and it has been somewhat variously defined by different authors. Rankin defines it as a derangement of function resulting from exhaustion of nervous energy. "Wear and tear," "storm and stress" of modern life—in fact, a badly regulated life—is one of the chief causes, but inheritance is also a very important factor in its causation. "Little is known," says the writer, "of the pathological conditions underlying the disease. Bouchard attributes the disorder to abnormal fermentations in a stomach which, in virtue of heredity or congenital weakness, of its muscular coat, contracts insufficiently in the intervals between different periods of digestion. Under these circumstances he believes that soluble toxins are produced, which, when reabsorbed, impair the anatomical elements of the different organs, and notably those of the nervous centers. Another theory suggests that the disease is due directly to vitiation of nutrition, the result of imperfect digestions. The dyspepsia need not, according to the advocates of this hypothesis, be necessarily associated with gastric dilatation, but it produces, sooner or later, anæmia, which, in its turn, gives rise to depression of the nutritive activity of all the tissues of the body, and more particularly of the newer elements. Glénard has endeavored to explain both the dyspepsia and the neurasthenic symptoms by a sinking of the viscera in the abdominal cavity, but, though enteroptosis exists in a certain number of cases, it is the exception rather than the rule."

"Whatever," Rankin proceeds to say, "the ultimate nature of the pathogenic origin of neurasthenia may prove to be, the functional disturbances which the disease produces appear to depend upon some primordial alteration of the nerve cells which we do not understand. Neurasthenia is most frequently met with between the ages of twenty and forty years, attacks men more frequently than women, and is especially apt to affect those of neurotic inheritance, or those who live under conditions of mental or physical tension." The treatment of neurasthenia should be conducted on the common-sense lines of altering one's mode of living for a time. In place of the hustle and bustle of modern existence—particularly of that which prevails in America—rest and quiet must be sought in the healthy open country, where the worn and jarred nervous system will have a chance to recover its tone, and the functions to perform their work as they should. It is not only the strain of city life, however, which injures many of its present-day followers, but the manner in which they eat and drink and otherwise dissipate.

---

Formaldhyde is unsuitable for the disinfection of rooms because (1) even under the most favorable conditions of temperature and moisture in general it yields only about 50 per cent. of positive results. (2) Disinfection is not equable throughout various parts of the room. (3) Where dust is visible disinfection occurs only exceptionally. (4) Dried sputum on walls or floors is rarely disinfected. (5) Disinfection of the floor almost never takes place owing to the tendency of the gas to rise. (6) Beds and mattresses are not penetrated by the gas. (7) Disinfection with formaldehyde must be followed by washing down with bichloride solution. (8) Disinfection with formaldehyde requires five to six hours and subsequent ventilation for several hours longer before the room is habitable again. (9) The use of formaldehyde complicates rather than simplifies the process of disinfection.—*Centralblatt für Bakteriologie.*

**Cockroaches as Conveyers of Typhoid Infection.**—Rose Engelmann presents the history of a house epidemic of typhoid fever that she believes was spread by cockroaches. She finds no other record of such portage in the literature. The source of the infection in the first case is uncertain, although it can probably be attributed to culinary and toilet use of the city water, that at intervals during the spring and early summer had been turned into the house mains when the artesian well pump broke down. The city water was also turned into the tank in order to wash it out. So the artesian well tank water and the house mains became contaminated. But if the infection was due in all these cases to the water supply, why was there no further incidence of the disease in the other twelve families, and why was it almost confined to the tier directly over the first case, unless the cockroach pest was in close relation thereto? The writer then traces the spread of this fever, pointing out its apparent relation to cockroaches, which swarmed through the house. She hopes that further investigations in this line will be taken up by bacteriologists.—*Medicine.*

# News of the Week.

**Report of the Illinois State Board of Health.**—This board has just issued its report of the births and deaths in the State during the year 1902, the report having been delayed on account of the failure of the county clerks to render reports to the State Board of Health in the manner required by law. In concert with all other registration States, Illinois has adopted the Bertillon classification of deaths, but this method of registration is quite complicated, and it was found impracticable to require county clerks to comply with the law. Dr. J. A. Egan, Secretary of the State Board, therefore requested the clerks to send the original death certificates to his office instead of the reports called for. These certificates have been recorded under the direction of the secretary with satisfactory results. Eighty-seven thousand two hundred and thirty-six births were reported, a rate of 17.90 per 1,000. The greatest number was reported from Lawrence County, where the rate was 31.09 to the 1,000. The rate in Cook County was 16.17 per 1,000. It is not claimed by the State Board of Health that these figures represent the actual number of births occurring in the State during 1902, for it is well known that many physicians and accoucheurs fail to report births. The results are considered satisfactory, however, for the first year of the registration law. These births were reported under a voluntary system of notification. The total number of deaths registered during 1902 was 61,144, a rate of 12.54 per 1,000. The Cook County rate was 13.84 to the 1,000, based on an estimated population of 1,968,097. The ten principal causes of deaths in the order of their importance were as follows: Tuberculosis, pneumonia, organic heart disease, accidents, kidney disease, gastroenteritis in infants, cancer, typhoid fever, cerebral congestion, and hemorrhage, diphtheria. The statistics show that 6,868 persons died of tuberculosis, this number being 11.23 per cent. of all deaths, or 1 in every 8.90 deaths. By age the destruction from this disease was greatest from twenty to forty years, 51.2 per cent. of the deaths being reported during this period. It is the opinion of the State Board of Health that the reported death rate from tuberculosis is too low, and that many deaths reported as pneumonia, bronchitis, and influenza were due to tuberculosis. These deaths were reported under the burial permit law of 1901, which required that a permit should be issued before the body could be interred. Permits were issued only on the presentation of proper death certificates. The reports, therefore, should be accurate, but it is believed by the State Board of Health that the number of deaths was greater than reported. Instances have been cited to the board in which the issuing officers failed to forward to the county clerk the death certificates presented to them. It is not known to what extent this practice has prevailed.

**Physicians as Public Health Officials.**—The wisdom of having physicians at the head of health departments is being again exemplified in the city of Philadelphia, where the director of the recently organized Department of Public Health and Charities, Dr. Edward Martin, has appointed a distinguished hygienist, Dr. A. C. Abbott, President of the Board of Health. Already these officials have taken steps to improve the water-supply and the food-supply and the sanitary conditions of the city generally, as well as the hospitals under their supervision. Public health has become a specialized field of activity, which no layman, however well equipped, is so well capable of administering as a physician.

**Philadelphia County Medical Society.**—At a stated meeting, held June 24, Dr. A. B. Kirkpatrick exhibited cases of nasal deformity treated with subcutaneous injections of paraffin. Dr. Chas. F. Nassau presented a paper entitled "Ligation of Subclavian Artery for Aneurysm of Second and Third Portions," and he demonstrated the patient.

**Vital Statistics of New York City.**—The vital statistics for the first half of the current year, recently made public, show a marked decrease in the death rate over that of the corresponding period of last year and an increase in the number of births reported. For the first six months of 1903 34,855 deaths were reported, indicating a death rate of 18.67 per 1,000 inhabitants. The number of deaths reported in the first six months of 1902 was 35,491, a death rate of 19.54 per 1,000. The births reported numbered 46,408, against 40,392 for the first half of 1902. This increase was due, in part, to the increase of population, but more probably to the more careful reporting of births, which has been strictly required of physicians and midwives.

**The Eleventh International Congress of Hygiene and Demography** will be held at Brussels from September 2 to 8 of the current year. The President is M. Beco, secretary-general to the Minister of Agriculture and chief of the Brussels Sanitary Department. The general secretary is Dr. Putzeys, professor of the Faculty of Medicine of the University of Liège, whose address is No. 1, Rue Forgeur, Liège. The hygiene division of the congress is divided into seven sections, viz., (1) bacteriology; (2) the hygiene of foods, including chemistry and veterinary matters; (3) sanitary technology, including engineering and architecture with reference to hygiene; (4) the hygiene of trades and professions; (5) the hygiene of railways, shipping, and other methods of transport; (6) administrative hygiene, including the prevention of transmissible diseases, workmen's dwellings, and infantile hygiene; and (7) colonial hygiene. The secretary of the American committee of organization is Dr. A. E. de Schweinitz, Washington, D. C.

**A Peripatetic Eye Clinic.**—It is stated in the *Lancet* that Sir Ernest Cassel has given a large sum of money to the Egyptian Government for the relief of ophthalmia in Egypt. In order to expend the money to the best advantage, it has been decided to send traveling dispensaries into the country for the relief of those sufferers who are unable to attend the already existing hospitals. There will be at first one of these dispensaries or ambulance hospitals, which will have a couple of tents with beds for patients who have to be operated upon, and for the treatment of the more serious cases. This will travel about from place to place under the direction of an ophthalmic surgeon, who will have under him an Egyptian assistant surgeon. Mr. A. F. MacCallan, chief clinical assistant at the Royal London Ophthalmic Hospital (Moorfields), has been appointed by the Egyptian Government to organize and to direct the enterprise with the title of "inspector of traveling ophthalmic dispensaries in Egypt." If this experiment is successful, other dispensaries will be organized and sent forth on their travels.

**Tetanus Bacilli in Blank Cartridges.**—Dr. Richard N. Connolly of the Newark (N. J.) Board of Health, recently examined blank cartridges such as are used in pistols to add to the noise of our Chinese celebration of the Fourth of July, and found that they contained the germs of tetanus.

**A Plague Ship at Marseilles.**—When the steamship *France*, from Buenos Ayres, arrived at Marseilles on July 1, it was found that some thirty rats on board had died of the bubonic plague. The necessary precautions were adopted to prevent any dissemination of the germs, and the crew was put under observation.

**The American Physical Education Association** held its annual meeting in this city last week. Dr. Luther Halsey Gulick, director of physical training in the public schools of New York City, was elected president.

**Hospitals Criticised by a Coroner's Jury.**—A coroner's jury in Washington, recently sitting on two cases of death by violence, added a supplemental report to its findings which severely scored the medical staffs of Freedman's and Washington Asylum hospitals. In both cases there was a fractured skull, one caused by an axe, the other by a hammer. In one case the diagnosis was nephritis, in the other it was a scalp wound, and after it was dressed the man went to his home, where he subsequently died.

**A Sanatorium Monopoly in the Madeira Islands.**—It is reported that the Portuguese government has received a proposal from Prince Francis Henry of Hohenlohe for the formation of a large company for the exclusive establishment and exploitation of sanatoria for the cure of consumption in Madeira. The proposal guarantees that one-third of the receipts shall be paid to the State, and that a forfeit of $100,000 shall be deposited with the Portuguese government. Two sanatoria are to be built within the space of two years.

**The Floating Hospital** of St. John's Guild made its first trip on July 7, leaving the foot of West Fiftieth Street, Manhattan, at 8 o'clock A.M. Only one floating hospital will be operated this summer. The service will alternate between the east and west sides of New York, and the service which has been maintained in Brooklyn for four years will be omitted.

**Radium Rays for Cancer.**—At a recent meeting of the Medical Section of the Royal Imperial Academy of Science in Vienna, a paper was read giving the details of cure of a case of cancer of the hard palate and pharynx by means of radium rays. The patient, who was treated at the University clinic of the late Professor Gussenbauer, was a man sixty-one years of age. He had long suffered from cancer of the palate and lip, and had repeatedly been operated upon, but without success, the disease returning, and each time demanding a more extensive operation for its removal. Finally, in the autumn of 1902, the surgeons of the Allgemeines Krankenhaus declared it was absolutely useless to operate again. One physician determined as a last resort to try radium rays, and treated the afflicted parts by exposing them to the light of radium bromide, the strongest radium preparation in existence. He was rewarded by a gradual and complete disappearance of the growth, which has not returned, now some eight months after the beginning of treatment. At the same meeting a case of melanosarcoma cured by radium rays was reported.

**A Convalescent Hospital for New York.**—In a building at the northern end of Blackwell's Island, formerly occupied by the Manhattan State Hospital, a hospital for convalescent patients under the care of the Department of Charities, was opened on July 1 by Commissioner Homer Folks. The building contains beds for forty men and thirty women, and the number may be increased with growing demands so as to accommodate seventy men and sixty women. Patients will be allowed to remain for three weeks under ordinary circumstances, but provision is made whereby a six weeks' convalescence can be arranged in exceptional cases.

**Orange Smallpox Hospital Burned.**—The main structure of the group of buildings erected in Orange, N. J., at the time of the smallpox outbreak, about two years ago, and used as an isolation hospital, was destroyed by fire on July 2, entailing a loss of $2,000. It was with difficulty that the destruction of the other buildings was prevented, as there are no hydrants nearby, and the fight had to be made with the chemical engine. But the firemen were enabled to save the office, laundry and kitchen buildings. There were no patients in the hospital at the time. The burned building contained several beds, linen, medical and surgical appliances, and a quantity of medicines, all of which were destroyed. It is thought that the building was set on fire intentionally.

**Medical Society of the State of North Carolina.**—At the annual meeting of this society, held at Hot Springs June 2, 3, and 4, the following officers were elected: *President*, Dr. H. B. Weaver, Asheville; *First Vice-President*, Dr. J. W. Long, Salisbury; *Second Vice-President*, Dr. John C. Rodman, Washington; *Third Vice-President*, Dr. S. F. Pfohl, Winston-Salem; *Secretary*, Dr. J. H. Way, Waynesville; *Treasurer*, Dr. Sikes, Grissom. The next meeting will be held at Raleigh in 1904.

**The Summer School in Philanthropic Work.**—The sixth annual session of this school, conducted by the Charity Organization Society of New York under the direction of Mr. Philip W. Ayres, opened on June 22, and will continue to July 31. The meetings will be held in the library of the Charity Organization Society, in the United Charities Building, Fourth Avenue and Twenty-second Street, New York, at 8.30 o'clock, six mornings in the week. The first half hour will be devoted to a discussion of the preceding day's work. The following subjects will be taught: Care and treatment of needy families in their homes; care of destitute, neglected and delinquent children; medical charities; institutional care of adults; neighborhood improvements. The Department of Medical Charities is in charge of Dr. Silas F. Hallock, and the following is the program of lectures to be given: "The Management of Contagious Diseases in New York," Dr. William Hallock Park of the New York Municipal Laboratory; "What the Charity Worker Should Know of the Treatment and Prevention of Tuberculosis," Dr. S. A. Knopf, New York; "Social Factors in the Prevalence of Consumption," Miss Lilian Brandt, statistician of the Committee on the Prevention of Tuberculosis, Charity Organization Society. If the conditions permit, Dr. Alvah H. Doty, health officer of the Port of New York, will take the members of the school on one of the days of the session to visit the quarantine station and explain its work.

---

**Serum Treatment of Scarlet Fever.**—Theodor Escherich reports the use of Moser's serum in 142 cases of scarlet fever. The results fully confirm those reported by Moser at Carlsbad. The acute symptoms rapidly subsided, the effect being first noticed in from four to twelve hours following the inoculations. The so-called septic symptoms (glandular enlargement, etc.) were the least influenced, although they never became of marked severity. As a general rule it can be said that complications (nephritis, etc.) are less marked in those cases treated with the serum than in those in which the ordinary measures are employed —*Wiener klinische Wochenschrift.*

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

DEGREES IN DENTISTRY—THE UNIVERSITY OF LONDON—EPILEPSY—HOSPITAL SUNDAY—SMALL HOSPITALS—THE CARLYLE CONTROVERSY—DARWIN'S LETTERS—DEATH OF DR. BIRKBECK NEVINS.

LONDON, June 19, 1903.

THE proposal to establish dental degrees in the reorganized University of London has been shelved for the present—and we may hope permanently.

There is no need of such degrees, and if one university begins others are sure to follow, and we shall be flooded with distinctions difficult to fairly value. If a dentist has a medical qualification, that ought to suffice with his L.D.S. (License in Dental Surgery). Perhaps I should put it the other way, the dentist has his L.D.S. If he desires anything more, all the qualifying bodies are open to him if he has fulfilled the curriculum for a medical or surgical diploma.

The L.D.S. has become now fairly familiar and will not easily be superseded. Besides, it is probable the university would have to obtain Parliamentary authority for instituting dental degrees, whereas it can already confer L.D.S. as other bodies do. If it must have a finger in the pie (or the pies), let it be content to do this. Surely L.D.S., Lond., would be distinction enough.

There were two proposals made—one to confer a dental degree only on bachelors of medicine and surgery, the other to admit to examination those who had not taken the final examinations for those degrees. The resolutions adopted by the faculty were only carried by a small majority, but it is to be hoped that specal degrees in special departments of medicine will not be instituted here or elsewhere.

The university has also been much divided as to the intended changes in the curriculum. The opponents of change went so far as to try to displace Sir T. Barlow, who was, however, re-elected to the Senate. The cry of the opponents was that the changes would lower the value of the degrees, and so it was repea'ed by those graduates who grudge an equal distinction to others and would maintain an absurdly high standard of examination as the one requirement for graduation. That system is one that develops cramming candidates with facts and opinions, but can scarcely be said to be a good method of medical education. It was largely the result of that system which brought about the reconstruction of the university.

The old university neither taught nor superintended teaching. It only examined, and the only way of making its degrees difficult to obtain was to make its examinations severe. A person, therefore, with a good memory and steady application could work up the subjects from well chosen textbooks and exhibit sufficient ready knowledge to satisfy any examiner. But that knowledge was not wisdom and too often it was forgotten as quickly as it was accumulated. Cramming for these degrees developed into a regular system and eventually a plan of preparing candidates through correspondence flourished. Whatever may be the value of such preparation, it cannot be pretended that it is the same as that of a residential university training.

Dr. Aldren Turner read an elaborate paper at the last meeting of the Medico-Chirurgical Society on the prognosis and curability of epilepsy. His paper was a statistical inquiry—the figures being obtained from the records of out-patients at the National Hospital for the paralyzed and epileptic. All cases were excluded (1) which had not been under observation for two years, (2) or were complicated with hæmiplegia, albuminuria, or gross cerebral lesion, (3) pronounced cases of idiocy or dementia.

The total number of cases thus obtained reached 366. Of these 86 were said to be arrested, 105 to show some improvement, and 175 to remain confirmed cases.

Among those who became confirmed epileptics a family history was more frequently recorded, but this did not seem to militate against the prospect of arrest or improvement in any individual case. Age is more important. The most unsatisfactory cases were those in which the disease began under ten; they showed the lowest percentage of arrests and the highest of confirmed cases. Arrested and confirmed cases showed an equal percentage when the disease began between fifteen and twenty. The highest percentage of confirmed cases began between twenty-five and thirty-five. As to duration, arrest or improvement is more probable in the first five years, but some cases have been arrested after twenty to thirty years. As to frequency of fits, the highest percentage of confirmed and the lowest of arrested cases were those subject to daily or weekly attacks, while the converse may be said when they occurred only once or twice a year. Major attacks seem most tractable. Marriage and pregnancy seem without influence, but the puerperium and lactation seem rather unfavorable times.

Long remissions are of favorable prognostic value, but must not be called cures. From the statistics Dr. Turner puts a period of remission for at least nine years as the term after which a cure may be considered to be established. Adopting this term, he regards 10.2 per cent. of epileptics as curable. In the cases in which arrest took place, cessation of the fits occurred within the first year of continuous treatment in over 50 per cent.

In the course of the discussion on this paper, Dr. Fletcher Beach remarked that the statistics supported the general view as to heredity. The large percentage of confirmed cases which began in childhood was an important fact which needed explanation. Night fits being less amenable than day, the question might be asked whether treatment could turn night into day cases.

Dr. Shuttleworth, medical officer of the School Board, gave some statistics of the disease in reference to education. Out of 340 cases, 17 per cent. were able to continue their school work; 27.5 per cent. were unfit for this, but could profit in special schools; 40 per cent. were institutional cases. He had only had one recovery.

Dr. W. H. Blake remarked that the disease did not seem more tractable than before the use of bromide was general. He thought the stomach sometimes at fault and for that employed sulpho-carbolate of sodium. When fits seemed at all associated with commencing menstruation, sodium salicylate seemed useful.

Dr. G. Newton Pitt said it was clear that no greater proportion of cures had followed the introduction of bromides. Also, cases treated without benefit for a year were not likely to improve to any extent. Relapse sometimes occurred after nine years. When a patient had been without a fit for two years, should he go on with bromide, and if so, in what dose? So, after four or five years the same question requires consideration.

Dr. Batty Shaw remarked that these statistics confirmed those of Sir Wm. Gowers as to heredity.

Dr. Turner, in his reply, said he looked upon the fits as one symptom. The prognosis depended more on the mental factor. He thought the obstinacy of child cases might be due to their mental state. He could offer no rule as to giving bromides after a period of remission.

Hospital Sunday was such a drenching wet day that the churches and chapels were very thinly attended and the collections necessarily suffered. The judges and the Lord Mayor attended at St. Paul's, where £119 was collected. At Westminster Abbey the amount reached £134.16. The hopes of a record year have accordingly faded. The Lord Mayor has asked the ministers to appeal to their congregations to make up next Sunday for their absence last Sunday. There is no promise of any remission in the terrible weather that has prevailed here all the week. We can only expect the more liberal donors to send their contributions to the Lord Mayor on Saturday.

Princess Louise, accompanied by the Duke of Argyll, opened the new building of the Hospital for Epilepsy and Nervous Diseases. This institution, founded in 1866, will have, when completed, sixty beds. The Duke said there would be no lack of support because the hospital is small. "Small hospitals in different districts were preferable to large barracks."

Whatever may have been your view of the Carlyle controversy, you will scarcely fail to be interested in the aspect given to it by the publication of the "New Letters and Memorials of Jane Welsh Carlyle," which is considered the literary event of the year here. My excuse for mentioning the work is that it is edited by Sir J. Crichton-Browne, M.D., whose professional contributions I have often mentioned. He takes a very decided view as to Froude's conduct.

The book will doubtless interest Dr. G. M. Gould, whose "Biographic Clinics" has come from your side, and contains suggestions as to the ill-health of Carlyle and other literary celebrities. Dr. Gould's book offers, also, an explanation of Darwin's case, and here again further facts appear on this side which occupy two volumes, with the descriptive title of "More Letters of Darwin. A Record of His Work in a Series of Hitherto Unpublished Letters." The work is edited by Francis Darwin and A. C. Steward and contains eight plates with a number of portraits and other illustrations. Darwin was a qualified doctor, you will remember, though he did not practise the profession. But he does not seem to have studied the accommodation of his eyes as Dr. Gould now does.

Dr. J. Birkbeck Nevins, of Liverpool, died on the 11th of June, in his eighty-fifth year. He studied at Guy's Hospital, took his M.B. London with honors in 1841, and M.D., 1846. He was surgical tutor at Guy's for some two years, and took two voyages to Hudson's Bay, an account of which he published in 1843. The next year he became lecturer at the Liverpool College, where he taught for

many years chemistry, physics, botany, and materia medica. His translation of the "London Pharmacopœia" held an honored place as one of the best textbooks until the advent of the "British" superseded it. His "Prescriber's Complete Handbook," chiefly translated from Trousseau and Reveil, was greatly esteemed.

Among the numerous offices he had filled in Liverpool may be named the presidency of the Medical Institute and of the Literary and Philosophical Society. Some of his contributions illustrate the wide extent of his knowledge and interest beyond professional subjects; *e. g.* "Revision of New Testament," "Historical Facts in Relation to the Prophet Jonah," "Arrangement of the Hebrew Camp in the Desert and Those of Edinburgh, Liverpool, and Manchester," "Wales During the Tudor Period."

Dr. Nevins was also deeply interested in the question of contagious diseases, and sent a paper on the subject to the International Congress of Hygiene in 1891, and a further paper to the Brussels Congress of 1899.

## THE ADVERTISING OF OPERATIONS IN THE DAILY PRESS.

To the Editor of the Medical Record:

Sir: Notwithstanding the fact that every medical society, county, State, and national, discusses the ethics of medicine—most particularly the time-honored clause of professional advertising, strongly condemning it in every particular—we can hardly read a village or city paper and not see where doctor so-and-so suffers himself without remonstrance to be exploited for some simple operation which any tyro can do, yet which sounds almost impossibly grand under the penciler's hand.

When medical societies were few, it was less talked of than now, but tacitly understood by the profession that this kind of advertising was unfair and wrong, and in wretched taste, and was a distinct violation of the high code of honor among medical men, and this alone kept such things strictly within the bounds of professional reading—things that do not appear in medical journals, because there is no merit or skill attached to their performance, but invariably appear in non-professional periodicals. In this day of news-gathering, the modest physician is too often dragged against his will into public notice, but in too many instances the accurate description of the operation shows that some initiated person helps to mold public opinion.

It is to be regretted that physicians are not more circumspect than to permit their names to appear in this connection. Strict obedience to the code gives us a narrow limit in this direction, and justly so, as our own merit, as recognized by others, should alone advertise us. Certain members of the profession have too frequently taken advantage of the fact that newspapers have gone daft on appendicitis and *x*-ray, and are now taking up and discussing the "Lorenz method," as they familiarly call it. These gentlemen engage in the unscientific, brutal, and unsatisfactory crushing into pulp a club-foot—a species of guess-work, blindly breaking and tearing whatever resists and poulticing the job with "plaster-of-paris," and the weekly report of this work in the town paper calls it "Lorenz operation." The notice of these things, entirely foreign to the mission of the ordinary newspaper, has done much harm in causing every crossroads doctor to try to get himself advertised as a surgeon with an appendix dangling at his belt, a fair exchange for a place in Abraham's bosom, or a crown of glory on the part of the deluded victim.

The writer is aware that this is a hackneyed subject, but it is like a good many old things in medicine—too nearly forgotten for newer and less worthy ones. The masses, even among the intelligent, are woefully ignorant of medicine and surgery, and when they constantly see some shameless doctor's name in connection with these wonderful (?) things they at once conclude that he is the only man in the community who can adjust a fracture or amputate a toe, and his henchmen (for such always have them) do the rest to make it redound to his pecuniary gain. If any member of the profession protest in these secular papers against his methods, that, too, he turns to his advantage by crying "jealousy and persecution." These things are doing much to lower the standard of medicine, for they are in high as well as low places.

X. B. Haynie, M.D.

Gallatin, Tenn.

## A QUESTION OF PRIORITY.

To the Editor of the Medical Record:

Sir: On June 15 of this year my attention was called to an editorial in the Medical Record of April 11, 1903, relative to a case of pneumonia supposed to have been treated with intrapulmonary injections of a normal salt-solution in August, 1893, by one Max Schüller of Berlin; etc. To say that I was astounded at this assertion is, indeed, but weakly expressing myself, and it was certainly beyond my belief that a medical journal so well informed as the Medical Record is supposed to be, and certainly is, could have come out with a column editorial lauding this foreigner and ignoring the priority of a fellow countryman. I still believe this to be an oversight, and feel sure that you will do your utmost to place the credit for this work where it rightly belongs. For protection, I have been compelled, at a great expense, to have an abstract made of every paper written and published by Max Schüller, and there has been absolutely nothing written by this man on the intrapulmonary treatment of the pneumonic lung. I enclose letter from the Newberry library showing the facts in the case. It seems strange that this man should attempt to do such a thing as this in the face of my European demonstrations, and the case reported by me in my paper already published, *Medical News*, June 21-28, 1902. He must give the scientists and medical editors of Europe and America credit of knowing little or nothing of what has been done along these lines up to this time. In Berlin some of the most eminent men told me they thought intrapulmonary injections of a salt-solution in the healthy or non-consolidated lung would cause œdema and death, and one or two could hardly believe the needle was in the lung when I demonstrated on the dog at Hospital Mobit. The same remarks were made at the Vienna, Paris, Madrid (Faculty of Medicine after reading my paper before the physiological section and the National Medical Association section), Rome, and London demonstrations. They, of course, knew of Lepines' work on the pneumonic lung, and also knew of the bad results obtained by his method. They did not seem to understand that rapid endosmosis would prevent œdema. This was perfectly clear to them after they witnessed a twenty-pound stream from the organometer being rapidly absorbed, and too without injury to the lung tissue, as I afterward showed them. It seems almost impossible that a man could call himself a scientist (for the word "scientist" means a searcher for truth) and stoop to do so small and unmanly a trick. If science has become so degraded, I want nothing more to do with scientific research. I have no doubt that he did the work as reported in the *Klinisch-therapeutische Wochenschrift* of Vienna, but Schüller did not do this work prior to June 21, 1902.

I am at a loss to know how a man who had obtained such remarkable results as Dr. Schüller reports in his paper could wait ten long years before reporting them. The entire affair to my mind is ridiculous in the extreme.

W. Byron Coakley, M.D.

100 State Street, Chicago.

[The article to which our esteemed correspondent takes exception was based upon a paper published in the *Klinisch-therapeutische Wochenschrift* of February 15, 1903. The topic was one of scientific interest, and was commented upon for that reason, with no thought as to priority in the therapeutic principle involved.—Ed.]

**Puerperal Eclampsia; a Plea for Treatment with Veratrum Viride.**—J. S. Hammond firmly believes, from his reading and from his observation, that when veratrum viride has been fairly tested, and by that he means given in doses to reduce the pulse to 60 or below, and holding it there, that its record of cures surpasses that of any other treatment ever yet tried. It accomplishes as marked and beneficial results as morphia and in an entirely different manner. Through its active principles, veratrine and veratroidine, it lays hold of the excited circulation and controls it completely, both in the matter of frequency and tension. This goes far toward allaying that irritation which excites convulsions. But this irritation is further controlled by the muscular reaction and prostration produced by the exhibition of veratrum. As a depressant of the vaso-motor nerve-centers, and as a spinal depressant as well, veratrum has no equal, except perhaps in chloral. Its action as a spinal depressant can be carried safely to a complete abolition of reflex activity. It will also cause diaphoresis, and is an eliminative through this means, and also by catharsis. Bleeding accomplishes nothing that is not accomplished by veratrum, but what it does is at the expense of impoverishing the blood, and this, too, in a malady already characterized by hydræmia. As against the danger of all other methods of treatment and all other agents, veratrum has this great overwhelming advantage that it is admittedly safe.—*Annals of Gynecology and Pediatry.*

*The Boston Medical and Surgical Journal, June 25, 1903.*

**The Cure of Cancer by the Use of the X-ray.**—H. W. Van Allen declares that after the *x*-ray has cured a cancer, we do not know yet if it will return. Cases are on record of seyeral years' standing, with no return. Thus far the percentage of returns is not so great as with the knife for the same period. Only after years can we tell the final result. All the cases treated by the writer, excepting two, have been cases that have returned, having been cut out previously. One writer states the percentage of recurrences after operation as 52. The prospect is that in thoroughly treated cases by *x*-ray nothing like this percentage will return. While this is the great item in judging the advantage in method, we should not forget the lack of disfiguring scar, the ease of application, not removing the patient from ordinary occupation, fear of the knife, etc. Such facts present an argument too strong to be put aside by even the most radical operating surgeon.

**The Blood in the Typhoid Fever of Children; a Clinical Study.**—Frank Spooner Churchill concludes: (1) The blood in the typhoid fever of childhood differs from that of adult typhoid only in degree. (2) The erythrocytes are reduced in number, especially during the first three weeks, after which they begin to increase rapidly, reaching normal in the fifth week. (3) The hæmoglobin suffers more proportionately than the erythrocytes. (4) The leucocytes are reduced throughout the first four weeks, the lowest average being reached during the second week, except in severe and tedious cases. (5) The leucopenia is of diagnostic value, especially in children, in whom most febrile affections produce a leucocytosis. More data are needed to determine the priority of appearance of a "positive" serum reaction or a leucopenia. (6) The relative proportion of the different varieties of leucocytes varies at different periods of the disease, the greatest variations being found in the polymorphonuclears and mononuclear elements, the former diminish and the latter increase as the disease advances. The increase in mononuclears is chiefly in the lymphocytes. Analysis of large numbers of cases grouped by age and week is desirable.

*The Boston Medical and Surgical Journal, July 2, 1903.*

**Nasal Polypi: A Study of One Hundred and Forty-Seven Cases.**—J. Payson Clark declares that his greatest hindrance in the study of these cases was the difficulty of sufficiently impressing upon patients the importance of following up treatment and reporting as often as desired for observation. The usual site of these growths is in the region of the middle turbinated bone, from some part of the outer wall of the nose concealed by the middle turbinate, but more often from the turbinate itself, either from the lower border or from the outer or (more rarely) the inner surface. The writer finds no evidence of any constitutional diathesis or impairment of the general health standing in any causative relation to this affection. Heredity appears to play no part. More than half of the cases were between thirty and fifty years of age. A neglected injury to the nose might conceivably result in polyps. Suppuration of one of the accessory sinuses is another predisposing cause of the growth of nasal polypi. All but about a fifth of the cases gave a history of frequent head colds. In a large proportion of cases, obstruction to respiration is the first symptom which calls the patient's attention to his nose. Sneezing was marked in about a third of the cases. The discharge varies from watery to mucous. The writer states that probably only a small proportion of cases are caused by sinus disease (usually ethmoiditis). A local vasomotor disturbance, which may be of constitutional origin, stands in a causative relation to polypi in a certain proportion of cases. The removal of the whole middle turbinate will be found necessary in many cases when the growths are diffuse. Many cases of nasal polypi can be cured if patients will return for treatment as instructed.

**Septic Endocarditis.**—A. W. Dudley reports this case. The patient was a girl of twenty-five years, well developed and well nourished, though pale. She had had albuminuria for three or four years. The specific gravity was 1015–1020. Sediment showed normal blood. Some granular and hyaline casts. Otherwise her organs were normal. The illness began with fever, rapid pulse, and some soreness and redness of the throat. There then developed a mixed macular, papular, and hemorrhagic eruption, mostly on the hands, forearms, feet, and legs. There were frequent chills. There were fleeting joint pains and some swelling of the legs The urine became high colored. The heart was negative. Malaria could not be excluded. The spleen was slightly enlarged. The heart showed a slight systolic souffle when in violent action only. At the end of the second week malaria could be ruled out. A blood culture proved negative. The systolic souffle became more distinct, was confined to the apex, not transmitted, and heard only when the heart was in violent action. There were a few short attacks of precordial pain. About two months after the beginning of her illness, for two weeks, though often greatly depressed and somewhat exhausted, there was no fever except for two days, and then not above 101°. There were two attacks of delirium. Alcohol, strychnia, at times digitalis, morphia, and good food were given. Coffee was craved and allowed freely. Unguentum Credé, was used. This diagnosis cannot be absolute, and is arrived at by exclusion fully as much as by positive signs. Since the illness she has had "rheumatism" of the legs. The association between tonsillitis and rheumatism, and rheumatism and endocarditis, is recalled by this case starting with a sore throat, showing rheumatic symptoms after a few days, and coincident therewith the septic fever curve. About two weeks after the beginning of the illness, a three-hourly chart was kept. For three weeks the pulse followed the temperature The interval between the crests of the fever waves varied from twelve to twenty-four hours, with one exception, and the crest of the wave rose from normal to 105° as the lowest and 106.8° as the highest. Convalescence was finally accomplished. There is no demonstrable region of the heart.

*Journal of the American Medical Association, July 4, 1903.*

**Influenza in Children.**—The conclusions of W. C. Williams are as follows: (1) Children of any age, even in early infancy, are susceptible to the influenza infection. (2) Repeated relapses and grave sequelæ are frequent in cases in which the initial seizure is mild as well as when it is severe. Therefore, no attack should ever be considered as "mild" nor as recovered from until a sufficient time has elapsed. (3) Clinical diagnosis should always be supported by the evidence of the microscope, whenever possible, as the practical certainty thus obtained may be of great value in explaining future developments.

**The Boy's Venereal Peril.**—Ferd. C. Valentine repeats the plea so often made for the proper instruction of the growing boy in regard to matters of sexual hygiene. He should know two facts: (1) That of all women who die of diseases of the reproductive organs, 80 per cent. are victims of gonorrhœa, of which their husbands imagined themselves cured. (2) That of all children born with seeing eyes who became hopelessly blind within a few days after birth, 80 per cent. lost their sight because of infection by gonorrhœa of which the fathers imagined themselves cured. All such information should be communicated at the time of puberty, at which time it will make the deepest impression. Other matters to which attention should be directed are: (1) The evidences of awakening genesic tendency. (2) Masturbation and the impulses or defects that lead thereto. (3) The evil influences that mislead youths into immorality. (4) Prostitution, public and clandestine, and the mental and physical destruction they bring. (5) Gonorrhœa, chancroid, chancre, and their sequelæ. (6) Advertising quacks, nostrum venders and an exposé of the methods they employ to swindle those afflicted with real or imaginary genitourinary and other ailments. (7) The reasons why a youth with a real or fancied illness due to immorality should consult a physician whom he knows, or whom his father knows. (8) The reason why reputable practitioners do not advertise.

**Fat Necrosis of the Kidney.**—J. R. Guthrie discusses the physiological chemistry of this condition and enumerates the causes leading up to it. He adds the history of a personal case, his patient being a single woman aged twenty-two years with a tumor-like mass in the left hypochondriac region extending down to two inches above the umbilicus. There was a progressive bodily weakness. Pressure would return the mass to nearly the normal kidney site. A lumbar incision was made, and the mass being brought up into the wound was there clamped. The capsule gave way and there was discharged from the kidney a yellowish semifluid substance to the amount of 12 to 14 oz., and resembling in color an emulsion of cod-liver oil and iodoform, containing a peculiar flaky or shredded material. By digital examination it was found that, practically, the whole kidney substance had been destroyed. The kidney was stitched into the wound, leaving free and unobstructed drainage. Some of this semifluid material drained from the kidney for several days. Some of the material saved for chemical and microscopical examination was found to be composed almost entirely of an emulsion containing oil, fatty cells, together with fibrous and connective tissue. A fatty substitution had taken place in the kidney, followed by

liquefaction necrosis, which had, practically, destroyed its secreting structure.

**Pityriasis Rosacea.**—L. Weiss gives a complete general description of this disease under the conventional headings. Under the head of differential diagnosis he mentions disseminated ring-worm and seborrhœic eczema as the dermatoses with which it is especially apt to be confounded. Concerning the latter he states that he has found that it will spontaneously yield scales even in places where it is exposed to maceration, while pityriasis rosacea will do this only when scratched. Syphilitic lesions leading to confusion in diagnosis from pityriasis are roseola and the macular syphilide. With psoriasis, pityriasis can be confused only in case of recent punctate lesions in persons who perspire freely, or in summer when the lesions are naturally moist. But on scratching we have here the punctate hemorrhages. As to treatment, Weiss advises against the general malaise, a saline cathartic; against the anorexia or other gastric and intestinal disturbance, the exhibition of diluted muriatic acid and nux vomica will be in order. If itching is complained of, bran baths and mild salves, probably with the admixture of salicylic acid or resorcin, are to be recommended, or spirituous lotions of the same drugs may be applied. The much-vaunted influence of higher percentuated salves with salicylic acid, resorcin, sulphur, naphthol, with a view of their parasiticidal virtues, is absolutely *nil*. There is no fungus to kill in this affection, and whatever changes these salves may elicit on the skin—bleaching and desquamation—are due to their reductive qualities of the remedies incorporated in them.

*Medical News, July 4, 1903*

**Tuberculosis of the Middle Ear, with the Report of a Case.**—Z. L. Leonard states that when the ear is the seat of a tuberculous process, it may precede a general systemic injection which later develops in the lungs or in parts remote from this location. Usually, it is secondary to an attack in other quarters which has progressed to an advanced stage. As to the symptoms, the grayish spots in the membrana tympani before it has ruptured; the multiple perforations; the rapidity with which the bone yields to disintegration and the absence of pain, are a combination of great importance. Tubercle has been found primarily in the mucous membrane of the middle ear and in the spongy tissue of the petrous portion of the temporal bone. The aspect of the perforation through the drum is diagnostic. As a rule they are two in number, but more have been observed. These openings soon run together. Deafness is noticed early, and is progressive. The treatment must be similar to that which would be pursued in any case of purulent discharge from the ear. Antiseptic, stimulating or by using astringents. Active measures should also be taken to elevate the general lowered condition. The writer then reports a typical case in which both ears were affected. Later the lungs became affected. It should be a routine practice to submit to the microscopist for diagnosis and verification the products of an unhealthy discharge not alone from the upper-air passages, but from the ears as well.

*New York Medical Journal, July 4, 1903.*

**Black Chromidrosis with Hysterical Paralysis.**—J. W. Putnam reports the case of a woman aged nineteen years well nourished, but with complete loss of power of both arms and legs, and cutaneous anæsthesia of arms, trunk, and legs. Patellar and plantar reflexes were preserved and not exaggerated. The Babinski sign was absent. There was no loss of bladder control, but the region of the spine was excessively irritable. Pressure over the ovaries caused pain. There was no tenderness at the supramammary and inframammary points. The face and neck muscles were not involved. The skin of the eyelids and malar regions, and the upper portion of the nose was inky black; as, also, was the edge of the mucous membranes of lips. The sensation of the skin was normal. The patient declared that these symptoms came on suddenly, when she was being stared at because of her peculiar appearance. Electricity was employed in various ways as well as suggestion treatment. Under this plan, together with general hygiene, she made a gradual recovery. Menstruation had been in abevance for some months, except for a few hours at the regular time of each period. The total period of amenorrhœa was fourteen months; that of chromidrosis nine months, and there were six attacks of recurring hysterical paralysis in that time at irregular intervals.

**The Hook-worm Disease in Alabama.**—E. D. Bondurant believes that uncinariasis is very common in Alabama, especially in the country regions and among the poorer classes of whites. The most prominent symptom is anæmia. The blood shows a diminution of hæmoglobin percentage out of all proportion to the reduction in number of the red cells. An excess of eosinophile cells has also been found. Almost as characteristic as the anæmia are the associated mental and physical feebleness, apathy, indifference, and inability and disinclination to work. Normal development is checked, the patients are generally undersized, and the growth of hair is scanty. Hæmic heart murmurs are frequent. Œdema of the feet and eyelids is often met with. The appetite is capricious, sometimes ravenous, and a liking for clay, chalk, dirt, and other indigestibles is shown. The bowel symptoms are not characteristic. There may be constipation or diarrhœa, or no abnormity. In many instances the fecal matter is blood stained, or colored by altered and partly digested blood which has oozed from the wounds made in the intestinal mucosa by the parasites. The "dirt eaters" of the sand hills are excellent examples of this disease, and any one who can recall the appearance and mental characteristics of a little, stupid, tallow-faced, dirt-eating boy, has a typical picture of uncinariasis. The diagnosis is confirmed by the finding in the discharges the ova of the hook-worm. Treatment calls for male fern or thymol as anthelmintics, and a persistent tonic regimen.

**The Treatment of the So-called Diabetic Gangrene of the Extremities.**—H. Lilienthal would group these cases as follows: (1) Patients with good general condition, no acid intoxication, variable amount of sugar; one or more toes or fingers with or without phlegmon not threatening the usefulness of the member. Here treatment should be conservative. The affected fingers or toes should be removed and the phlegmon freely laid open. The wounds should be packed and wet dressings applied, the tendon and fascia being allowed to slough away. (2) General condition good; no acetone or diacetic acid in the urine; local condition such as to threaten the usefulness of the affected member. Here the ablation of the limb high above the upper level of the disease is the proper course. When the disease is in the foot it is best to make the amputation well above the knee, because at the knee-joint there is so much tendinous tissue that necrosis is extremely apt to appear in the stump and defeat the aim of the operation. In the upper extremity the amputation need not, however, be above the elbow for a mere gangrene of the hand. All flaps should be made of skin and muscle instead of being composed of skin alone. (3) General condition of the patient poor or comparatively good; sugar in variable quantities; acid poisoning present; disease threatening or not, the affected part. Treatment here should be palliative until the acid intoxication with its impending coma shall have passed off. If, in spite of all our efforts, this cannot be brought about, the very poor prognosis should still deter us from radical operative procedures. Naturally, this does not mean that no efforts to promote drainage should be made. On the contrary, the free incision of tissues impeding the free evacuation of phlegmonous spaces must be practised in any event. But no more than is absolutely necessary should be done. Above all, no radical operation.

*American Medicine, July 4, 1903*

**Prophylaxis and Treatment of Baldness.**—Albert Bernheim presents the following conclusions on this subject: Bladness should not be treated as a joke, especially by the physician. Baldness is infectious and contagious. It can be prevented by prophylaxis. It can be cured in a treat number of cases in persons under fifty, and a trial is worth while in persons above this age. Patience in the patient is a condition *sine quâ non*, and in the physician is an absolute necessity. The etiology of baldness is not clear. Probably the exclusion of light and air from the hair has much to do with the predisposition to baldness. The writer's treatment is as follows: Time, patience, and tar soap. The soap is made from a prescription which contains about forty parts of birchwood, tar, or, better, beechwood tar to a soap mixture of sixty parts. With this tar soap the scalp should be shampooed every day for at least eight weeks, later on every other or every third day for another four or eight weeks. Shampooing must be thorough. The hair is patted dry, not rubbed. The scalp should now be rubbed with a solution of mercuric chloride, 1.0 to 300.0; glycerin and cologne spirits, each 100.0. The rubbing should be done with soft woollen tissue. Then the skin is rubbed dry for an another five minutes with a solution of beta naphtol, 1.0, and absolute alcohol, 200.0. After this the following hair oil is very freely used: Salicylic acid, 2.0; benzoin tincture, 3.0; neatsfoot oil, 100.0.

**The Early Diagnosis of Pregnancy.**—J. J. Gurney Williams states that the majority of patients consult a physician on account of amenorrhœa. He discusses this subject under three heads: (1) Menstruation has never been established. (2) Menstruation has been suppressed. (3) Retention of the blood within the

uterine cavity or vagina, as from an imperforate hymen. In those women in whom menstruation develops late, it is often found that there has been no sign of the menses till after marital relations have taken place. Change of climate often causes temporary amenorrhœa, as will also a fear of impregnation in the single, and desire for offspring in the newly married. In hard-working college girls, and in those who are musical and practise for hours, menstruation is often delayed. Amenorrhœa, arising from any cause other than pregnancy, usually shows itself in some constitutional disturbance as anæmia, general debility, and weakness. The mammary signs of early pregnancy are not constant and are often misleading. The nausea of pregnancy is usually of sudden onset, appearing when first assuming the upright position in the morning, or when awakening; it is generally of short duration, and accompanied by a feeling of dizziness. Some patients feel it only before retiring. The most important and reliable objective symptom of early pregnancy is found in the change of shape in the uterus. The uterus, which is not the seat of an ovum, feels like a funnel, the cervix broadening gradually into the broader fundus, whereas in the pregnant uterus the finger appreciates flattening of the lower uterine segment. This is felt on all sides, but far more distinctly, laterally. This sign can be felt as early as the fifth week, but it can only be appreciated between uterine contractions. Two other important symptoms are a cervix lower than the normal, and increase in weight of the uterus. Hagar's sign is at times misleading, and not always felt. Examination must be made for ectopic pregnancy. In the vast majority of cases an exploratory incision will not harm a normal pregnancy, but it will start us on the only road for saving life in an ectopic gestation.

*The Lancet, June 27, 1903.*

**Respiratory Crises in Graves' Disease.**—Two cases are given in detail by J. G. Sharp. In both the respirations succeeded each other with great rapidity, not less than sixty per minute, the conditions being not unlike those seen in atropine poisoning. It is found that opium has a marvelous effect in quieting these crises. The author would explain them on the supposition that in Graves' disease a poison is thrown into the system which under ordinary circumstances is excreted and produces only the ordinary symptoms of the malady. When an accumulation of the poison occurs, either from excessive formation or lessened excretion, we have a gastric crisis. When the accumulation is less or the excretory organs are unable to eliminate it, and it gets to the respiratory center, we have a crisis in breathing. Presumably the poison is its effects on the respiratory center analagous to strychnine. To this action, that of opium is antagonistic; hence the good effect of the latter remedy under the conditions specified.

**On the Diagnosis of the Cause of Jaundice.**—Sidney Phillips says that the first step in the diagnosis is to determine whether or not there exists obstruction of the common duct. Such obstruction is evidenced by (1) absence of bile from the stools, (2) enlargement of the gall-bladder, and (3) enlargement of the liver. He thus enumerates the causes giving rise to obstruction: (1) Morbid conditions involving the duct or its orifice in the duodenum: (*a*) catarrh; (*b*) duodenal ulcer; (*c*) duodenal cancer; and (*d*) stricture of the duct. (2) Foreign bodies in the common duct: biliary calculi, pancreatic calculi, and parasitic structures. (3) Pressure on the duct from without: (*a*) by perihepatitis and resulting adhesions; (*b*) by tumors, aneurysms, or enlarged glands in the portal fissure; and (*c*) by disease of the pancreas. Several illustrative clinical cases are given. Jaundice without obstruction in the common duct may be referred to (1) poisons circulating in the blood, such as phosphorus, toluylendiamin, etc.; (2) toxins resulting from certain diseases—yellow fever, the exanthemata, pyæmia, etc.; (3) congestion of the liver; (4) hepatitis; (5) acute atrophy of the liver; and (6) conditions of the nervous system.

**Note on the Persistence of the Gruber-Widal Reaction in Convalescence from Typhoid Fever.**—H. S. Brown and K. E. Crompton give a table of sixty-eight cases of typhoid fever showing the serum-reaction at various periods after recovery. Only three cases gave a positive reaction and of these one was obtained only two months after the attack. This is a much smaller proportion of positive reactions than is given by other observers, but the difference is due to the inclusion by the latter of cases, in which only a few weeks had elapsed since the original attack, and partly to the low dilutions used by them. The authors state that if they had considered a positive reaction with 1 in 10 sufficient their list would have shown eight more positive reactions, bringing our proportion up to 11 out of 68. While, however, they have no doubt that the reaction with the low dilution shows that the blood in some cases retains for a long time the specific agglutinating action on the bacillus typhosus, yet they wish to insist that this need lead to no error of diagnosis provided that sufficiently high dilutions—*i. e.* 1 in 20 or 1 in 50—are proceeded with in cases in which there is any doubt. Elsberg states that he found no relation between the severity of the attack and the duration of the reaction. Their own observations are in accordance with this. Many of their negative results were obtained from cases which had had severe attacks, often with relapses, while the patient in whom the only positive result, which cannot be explained on other grounds, had been obtained suffered from a mild attack without complications or sequelæ. They incline to a belief in the theory that the persistence of the reaction is due to the continued presence of the bacillus typhosus in the gall-bladder and elsewhere long after the original attack of fever.

**The Prevalence of Pneumonias in Infancy.**—S. V. Pearson believes that it is now generally recognized that croupous pneumonia in infants is far more frequent than was formerly supposed. Its recognition is importance from the point of prognosis, for the latter is better in infants than is the case with bronchopneumonia. Pearson goes so far as to say that croupous pneumonia is more common in infancy than at any other age. At the Shadwell Hospital in East London during the three years 1899–1901 311 patients were admitted suffering from croupous pneumonia. Of these 121—*i. e.* 40 per cent.—were under two years of age, 137 were between two and six years (a large proportion of these were patients between two and three years of age) and 53 were between six and fourteen years. It is obvious, says the author, from these figures that amongst children the commonest age-period for croupous pneumonia is during infancy. During the same period 230 cases of bronchopneumonia were admitted. Of this number 172 were under two years of age, 56 were between two and six years, while only two were over the latter year. These figures are from an institution in which very few infectious diseases are treated. Consequently the relative frequency of croupous pneumonia appears higher than is actually the case. Pearson sees no reason why the pneumococcus may not set up a broncho- as well as a croupous pneumonia. Some cases of pneumonia diagnosed as croupous, more especially in those babies who die, are really cases of primary bronchopneumonia; for in the primary bronchopneumonia sometimes the disease spreads so rapidly and signs of consolidation become evident so soon that it may simulate very closely acute croupous pneumonia, especially should the signs be limited chiefly to one lobe. The likelihood of mistaking a primary bronchopneumonia for croupous pneumonia is further rendered possible by its occasionally having a quite sudden onset, by its being sometimes associated with fever of the continuous type, and by the fact that it is usually of pneumococcic origin. But the opposite error of mistaking a croupous pneumonia in an infant for a bronchopneumonia is equally common, and probably outside of hospitals for children it is the commoner mistake. Moreover, another difficulty arises sometimes from the occurrence of intermediate forms. In the majority of these, in all probability, both varieties of pneumonia are present in different parts of the same lung or in opposite lungs at the same time.

*British Medical Journal, June 27, 1903.*

**Chickenpox Eruption on the Conjunctiva.**—Allan C. Pearson reports this occurrence in a child of two and a half years. It was in the form of a distinct pock on the bulbar conjunctiva at the outer canthus of the right eye. The eruption was present on the mucous membrane of the mouth, and there was marked enlargement of the lymphatic glands all over the body. The disease ran its usual mild course.

**Turpentine in the Treatment of Pneumonia.**—W. Thomas has used this drug in these cases for years, and regards it almost as a specific. After an efficient dose of calomel, he gives the following mixture: Ol. terebinth. pur., ℥ii to ℥iv.; pulv. trag. co., ℥i.; spt. amm. arom. and spt. chloroformi, ää ℥ii; aq. ad. ℥viij. M. sig., two tablespoonfuls every four hours. The virtue of the drug probably lies in its antiseptic properties, and the ease by which it is absorbed. It is a safe and most effective remedy in this, one of the most fatal of acute diseases.

**Potassium Permanganate in the Treatment of Lupus.**—J. Hall-Edwards has recently treated several cases of lupus with potassium permanganate, and has been surprised at the results. In several typical cases of large areas of lupus, in which the centers of the patches had undergone cicatrization, while the edges had been marked by a thick line of dry crusts, two applications caused the crusts to fall off, leaving a dry, healthy scar behind them. This treatment appears to have little or no effect upon those

indurated, shiny, non-ulcerative, slowly growing patches, which are so difficult to treat with either light or the *x*-rays. As an adjunct to *x*-ray treatment the writer considers potassium permanganate invaluable. He has not noticed any staining.

**Etiology and Treatment of Mucomembranous Colitis.**—Bottentuit states that mucomembranous colitis occurs at all ages. Doubtless constipation plays an important part in the affection. Faulty digestion is an important agent of infection and auto-intoxication. All persons of an arthritic diathesis are subject to catarrhal irritation of the mucous membrane. This affection is sometimes a sequel of enteritis and dysentery. The diet ought to be the same as is given in gastrointestinal dyspepsia or in dilatation of the stomach. One of the best laxatives is castor oil. In case of diarrhœa, bismuth salicylate should be used, and the intestines should be washed out and mild antiseptics given; when there are paroxysmal crises, hot compresses on the abdomen, poultices, and frictions with belladonna, should be prescribed. Baths are also a source of great relief. In the treatment of this affection the special indications must be considered, to which the different complications give rise.

**The Etiology of New Growths.**—Keith W. Monsarrat sums up his paper as follows: (1) Cell activity and cell type must always be the resultant of biochemical reaction of the principles of which the researches of Ehrlich and others have enabled us to obtain some information. (2) Cell proliferation as a form of cellular activity is always the resultant of such reaction. When it takes place as the result of increased availability of normal food material, the new cells produced conform to the type of the parent cells. When it follows the action of assimilated materials of abnormal constitution, new cell types are evoked, variants on the type of the parent cells. (3) Cell proliferation of the latter type takes place in certain microparasitic infections. (4) The new cell types thus evoked exhibit various degrees of instability. (5) In the granulomata their stability is considerable; in certain growths which result from infective agents (for example, condyloma) the equilibrium of the new type appears to be stable. (6) In the so-called true tumors, cell-types arise as variants on the normal cells of the organ or tissue of origin. The ways in which such cell variants may be evoked is not discussed, but that they may result in some cases from the action of microparasites, is a reasonable view. (7) These cell types are stable; their stability is due to the capacity of the particular variant to attach to itself and assimilate material in conformity with its type. (8) In the simple tumors they are only locally stable, and are not immune to reactionary influences outside the tissue of origin and the normal relationships of parenchyma and connective tissue. (9) In the malignant growths they possess a wide range of stability and immunity, and the degree of this is the measure of their capacity to form metastases, while local infiltration, the other histological characteristic, is dependent on the principle of chemiotaxis, the cells extending in those directions in which their variant and aberrant biochemical affinities enable them to annex material conformable to the building up of their characteristic type.

*Deutsche medicinische Wochenschrift, June* 11, 1903.

**The Latest Operation for Incurable Vesicovaginal Fistula.**—Edm. Rose reviews the literature of the operative treatment of vesicovaginal fistula, and gives as his most recent method a procedure which involves (1) the longitudinal obliteration of the vulva, and (2) the production of the so-called "large intestinal urethra," which means that the bladder is drained into the large intestine, and the urine evacuated per rectum. By this method, permanent results are obtained, and the sufferers are transformed from chronic invalids into persons capable of pursuing their ordinary avocations. Three cases are reported which substantiate the views advanced.

*Berliner klinische Wochenschrift, June* 15, 1903.

**Treatment of Phthisis.**—Th. Sommerfeld is enthusiastic concerning the use of the fumes of eucalyptus, sulphur, and charcoal in the treatment of pulmonary tuberculosis. The results following this inhalation are in the majority of cases beneficial. The cough and the night sweats are the first symptoms to be affected, and these are much lessened in intensity within a very few days after treatment has been begun. Following this there is a rapid reduction of the bodily temperature, and a gradual but progressive increase in weight. While this remedy cannot be regarded as an antituberculous specific, it is, nevertheless, of great value in the symptomatic treatment of phthisis, and the author thinks it is certain to win its way to extended use.

*Münchener medicinische Wochenschrift, June* 16, 1903.

**Acute Intestinal Obstruction Caused by Ascaris Lumbricoides.**—M. Schulhof's case was attacked with typical symptoms of appendicitis and was operated upon therefor. Upon opening the abdomen the appendix was found to be normal. After closing the wound the patient began to vomit ascaris, and within a short time, twenty-two of these worms were thus evacuated to be followed by a complete cessation of all symptoms and rapid recovery.

**Babinski's Tendon Phenomenon.**—Alexander Richter, after the examination of many hundreds of healthy and sick persons, says that the diagnostic value of this phenomenon is certainly very great, although it can by no means be regarded as absolute, since in 500 normal individuals it was found positive in 1.8 per cent. Its presence in any given case signifies the probable existence of alterations in the functions of the pyramidal tracts. The author is not able to decide as to whether by its means organic may be differentiated from functional paralyses, because of his inability to test it on any cases of hysterical paralyses, but the observations of Tumpowsky, König, and Cohn show that the same is extremely doubtful.

**A Malignant Epidemic of Scarlet Fever.**—Günther relates his observations of 150 malignant scarlet fever cases, which occurred in the recent epidemic at Höchstadt. The epidemic was remarkable for the high age of the patients attacked (many being adults), for the short duration of the fatal cases, and for the pronounced nervous symptoms present. Many cases died within twenty-four hours from the time attacked, and before the appearance of the eruption. The initial symptoms were vomiting and profuse diarrhœa, accompanied by high fever. Delirium and convulsions soon developed, to be rapidly followed by coma and death. The chief subjective symptom was pain in the throat, and intense tenderness of the neighboring glands. In those cases which survived until the appearance of the eruption, the same was scanty and of a dark, dusky color. In the non-fatal cases, kidney complications were extremely frequent during convalescence. Several cases are reported in detail.

*French and Italian Journals.*

**Lesions of the Nervous System in Human and Experimental Tetanus.**—G. Padoa concludes that in fatal cases of tetanus there may be no lesions or only very insignificant ones of the nervous system. The major lesions found cannot be held to be specific to tetanic intoxication, because of their inconstancy and the absence of all special characteristics. They may often, in fact, be due to certain phenomena that frequently accompany tetanus, such as asphyxia, uræmia, hyperpyrexia, etc.—*Rivista Critica di Clinica Medica*, June 13, 1903.

**Obesity from the Point of View of Life Insurance.**—M. Norton holds that an obese person, with perhaps the exception of a Jew, is an extra hazardous risk, his expectation of life being less than that of a normal individual. Women are as poor risks as men under these circumstances. Each applicant should be judged individually, the personal and family history being taken into consideration. If the obesity is due to alcoholism, although the alcohol be taken in small amounts but continuously, the applicant should be rejected.—*La Médecine Moderne*. June 17, 1903.

**The Treatment of Renal Lithiasis.**—An editorial states that the first rule to be followed in the treatment of this affection is to constantly examine the urine; if it is acid, prescribe alkalies and a vegetable diet. If alkaline, stop the medication and return to a meat diet. If there is too much urea, diminish the amount of food, and let what is taken be vegetable. If the amount of urea is too small, prescribe exercise and a suitable diet. If there is too scanty urine, give diuretics. Regulate the digestive apparatus by laxatives, care for the nervous system by hydrotherapy, and watch out in every way to see that the patient is suitably placed as regards mental and moral hygiene.—*La Tribune Médicale*, June 13, 1903.

**Atrophic Coryza.**—E. J. Moure has found that in cases of ozenatous atrophic coryza in the active stage, submucous injections of paraffin may be tried with a view to the reconstruction of the turbinated bones. This remedy has also proved of use in diminishing the secretion as well as the disagreeable odor. The secretion gradually becomes modified, and then as the patient is able to clear the nose with less difficulty there is no further formation within the nose of the offensive crusts. There is little doubt that paraffin treatment is destined to render great assistance in the management of the atrophic forms of coryza.—*Journal de Médecine de Bordeaux*, June 14, 1903.

**Migraine.**—M. Kovalefsky holds that the pathological hereditary predisposition to migraine is simply a per-

manent and excessive excitability of a certain number of vasomotor and sensory centers in the medulla oblongata, manifesting itself on one or the other half of the head, and often exaggerated by illness, cachexia, gout, etc. His radical treatment consists, in the first place, of a vegetable and milk diet, carried on for a period of years, early rising and plenty of sleep; no tobacco. Every day or two there should be galvanization of the cranium in an ascending direction. Hydrotherapy is a valuable adjunct. Bromide of sodium should be administered with interruptions of the treatment at intervals, for a period of two years, in doses of not less than two grams a day, associated with the tincture of strophanthus, and with cocaine.—*Tablettes Médicales Mobiles*, June 16, 1903.

**Bacteriuria.**—Luigi Ferrannini examined the urine of a rabbit and of six dogs under various conditions. Microorganisms were found in all the specimens. Sixteen different species of bacteria were isolated, one, *Micrococcus candidus*, having been found in two cases. The one pathogenic microörganism (*Micrococcus tetragenus*) was found in a dog whose urine had the greatest number of species, and which had been reduced to the death point by injections made to induce glycosuria. None of the animals had cystitis. Some of the dogs had urethritis, but their urine did not show a greater number of bacteria than that of the other animals. It is therefore evident that microorganisms are to be found normally in the bladder. As to whether they originate in the urethra, the kidneys or the blood, that will have to be determined by further experimentation.—*La Riforma Medica*, June 10, 1903.

**Adrenal Extract.**—G. A. Weill advises the use of adrenal extract with cocaine (1 to 200 or 100 solution of cocaine to a 1 to 2,000 or 1,000 solution of adrenal extract) in minor surgery, giving it hypodermically. The action of the cocaine is greatly increased while the condition of ischæmia induced by the adrenalin extract permits of a dry operation. The adrenal preparation also prevents absorption of the cocaine. A solution of adrenal extract, 1 to 1,000, is suitable for application on mucous surfaces. It arrests hemorrhage and to a great extent reduces hypertrophy of the tissues. As a general therapeutic agent its indications are limited to accidents due to chloroform, and to certain deeply-seated hemorrhages due to a morbid condition of the hæmatopoietic organs. It is better to administer it intramuscularly than through the stomach. Should the drug cause syncope the patient must be placed in a recumbent position, with loosened garments. Should more serious accidents follow, subcutaneous injections of ether are to be administered, and energetic friction of the body.—*Revue de Thérapeutique*, June 15, 1903.

**The Association of Appendicitis and Cholecystitis.**—G. Dieulafoy bases his remarks upon the study of about thirty cases in which these two affections occurred. The question is, are they really simply simultaneous in appearance, occurring from some one cause, or does one affection induce the other, and if so, which is the first to occur? The author's conclusion, after reviewing the evidence, is that the infection is not an ascending, but a descending one, and that the cholecystitis is the cause of the appendicitis. In twenty-five out of the thirty cases the symptoms of the biliary lesion were the first to appear, those of appendicitis being secondary, and coming on in a few days, weeks or even months. A new chapter is thus added to both diseases, and the physician must be continually on the watch in case of cholecystitis, lest while he is taking his time to treat this affection, the far more dangerous one may be insidiously making its appearance, and suddenly complicate matters by its toxi-infectious accidents, compromising the life of the patient and calling for prompt surgical interference.—*La Presse Médicale*, June 17, 1903.

**The Use of Vanadic Acid, More Especially in Gynecology.**—M. Le Blond and Ch. David have found that chemically pure vanadic acid is a medicine which deserves high rank among medicaments. While antiseptic in its action, it has the quality of assisting cicatrization to a marked extent, which renders it superior to all other dressings in the treatment of cutaneous wounds. 0.05 gm. to a liter of water is the proper proportion for this purpose. It gives good results when used topically in gynecology, and while it cannot be said that it is superior to all other known substances in use, it should be given the preference because of its absence of odor, and because it is better tolerated. The best solution for this use is obtained by adding to a volume of oxydasine (the commercial name of the 0.5 solution used by the author), two volumes of glycerin, this corresponding to a solution containing gm. 0.17 of the active agent per liter. In general practice, this substance is a valuable adjuvant in the treatment of pulmonary tuberculosis, the dose consisting of two tablespoonfuls a day of a solution containing gr. 0.015 to the liter.—*Bulletin Général*, June 15, 1903.

**Respiratory Insufficiency in Pulmonary Tuberculosis.**—M. Mendel has for several years treated tuberculosis by tracheal injections of the essential oils (essence of thyme, of eucalyptus, etc., in a solution of olive oil, preference being given to eucalyptus). A study of the results of this treatment has convinced the author that the irruption of the medicament in the respiratory passages of a tuberculous patient has for its immediate result a considerable enlargement of the thoracic respiratory area. This dilatation, under continued treatment, becomes permanent. In some cases this result is not obtained; the sensation of the patients themselves may serve as guide, for in the cases which are likely to receive benefit from the treatment, there is a speedy sense of well-being, and a power of larger breathing capacity, and of exercising without breathlessness. The cases treated by the author were all in Paris, not in any mountain or sea resort. The air of a large city is all-sufficient for these invalids, providing that the respiratory apparatus is in fit condition to receive and use it. It stands to reason that the best results obtained are in cases which are subjected to treatment before too large an area of pulmonary tissue has become involved.—*Archives Générales de Médecine*, June 16, 1903.

*Annals of Surgery, May, 1903.*

**Contribution to the Literature of Old Irreducible Dislocations of the Shoulder-joint.**—Seven cases are detailed by A. F. Jonas. His plan of treatment consisted chiefly of, first, manipulation. Using the forearm as a lever, rotating outward and inward, abduction and adduction, never forgetting for a moment a possible accident to the axillary vessels and nerves, and the possibility of fracturing the humerus. If this plan failed, second, through incision the capsule and all cicatricial tissue were extirpated. All muscular attachments that offered a restraint were severed, the axillary vessels were protected with a broad, flat retractor, and the head of the bone was brought into place by means of an elevator assisted by manipulation and traction. To avoid infecting the wound in this last manœuvre, it is advisable to firmly wrap the entire arm and hand with wet sublimate towels. Dry towels are liable to slip and become displaced, making it possible for the operator's hands to become infected. If the head cannot be replaced, then, third, the head of the humerus should be resected. This is an operation to be avoided when possible, on account of the resultant flail-like condition of the arm, and yet must be done (*a*) when the humeral head and neck become too extensively stripped of their attachments, experience having shown that necrosis may occur in 16 per cent. of the cases; (*b*) when osseous union has occurred between the head and the ribs; (*c*) when, after a division of all the restraining, soft parts, the head rests against the point of the acromion process.

**Hepatic Syphilis from a Surgical Standpoint.**—C. G. Cumston discusses the symptomatology and differential diagnosis of this affection and says that before surgical intervention should be seriously considered, the medical treatment should be thorough. The patient should use one gram of the ointment and take three or four grams of the iodide daily. When this treatment remains unsuccessful, even if we are in the presence of a gummatous liver, it is because the gummata are so old and the tissues have become so changed that medical treatment is without avail, and under these circumstances the question of surgical interference may very properly be considered. It is hardly necessary to say that not all gummatous tumors of the liver which have resisted all treatment can be removed by operation, because, in order to be able to extirpate them, the tumor must form a single mass, and numerous deposits scattered here and there in the liver substance would render it impossible to remove them all. Besides this, the location of the tumor in an accessible point is nesessary—that is to say, either in the left lobe or on the convexity of the right lobe. What is particularly essential is that the tumor be not profoundly situated in the hepatic parenchyma, because in this case its removal would necessitate such a destruction of the organ that the patient's life might be in danger. But in those cases in which the gumma is only covered by a thin layer of parenchyma, resection is without danger, and relatively an easy matter. In cases of pedunculated gumma the operation is fairly easy when the growth has sprung from under the surface of the liver, for little or no injury is done to the hepatic tissue, and consequently with a good ligature there is practically no danger of hemorrhage. Several illustrative cases are given.

# Book Reviews.

MUCOMEMBRANOUS ENTEROCOLITIS. By MAURICE DE LANGENHAGEN, M.D., London: J. & A. Churchill, 1903.

THE present monograph deals with membranous enteritis, a disease which is not very rare and in which the author seems to have had vast experience. According to Langenhagen, gingival aphthous manifestations are particularly frequent in membranous enteritis. When the malady is very serious, gingivitis is almost a permanent symptom: when the malady progresses—as it generally does—by fits and starts, each renewed attack of the complaint is accompanied by a corresponding attack of gingivitis. And this is so constant that I am almost tempted to say that, if the lingual mucous membrane is the mirror of the stomach, the bucco-gingival mucous membrane is the mirror of its congener, the intestine. With reference to treatment Langenhagen lays much stress on a very rigorous bland diet, forbidding fruits and vegetables. Occasionally he keeps his patients principally on milk. In this respect the writer of the book is not in accord with many modern clinicians, as, for instance, von Noorden, Ewald, Einhorn, and Boas, who permit a very liberal diet.

A SYSTEM OF PHYSIOLOGIC THERAPEUTICS. A Practical Exposition of the Methods Other than Drug giving Useful for the Prevention of Disease and in the Treatment of the Sick. Edited by SOLOMON SOLIS COHEN, A.M., M.D., Senior Assistant Professor of Clinical Medicin in Jefferson Medical College; Physician to Jefferson Medical College Hospital. Volume X.

PNEUMOTHERAPY, Including Aerotherapy and Inhalation Methods and Therapy. By Dr. PAUL LOUIS TISSIER, One-time Interne of the Paris Hospitals; Assistant Consulting Physician to Laennec and Lariboisiere Hospitals; Chief-of-Clinic in the Faculty of Medicine of the University of Paris. Philadelphia: P. Blakiston's Sons & Co., 1903.

PNEUMOTHERAPY is a branch of physical and physiological treatment which has not received much attention in this country. For this reason more space is devoted to the history of its development in the opening chapters than one finds similarly utilized in the volumes which have preceded. Divergent views are stated and discussed in relation to many subjects connected with pneumatic cabinet treatment, the effects of high altitudes, and often a quasi-judicial decision of the merits of a controverted subject is given. Inhalation methods in connection with certain aspects of pharmacology are carefully considered, showing a desire not to antagonize, by the methods proposed, valuable and discriminating treatment by drugs. The greater portion of the chapter has to do with conditions under which inhalations prove valuable and methods of preparing and administering the varied inhalants. It requires 478 pages to put before the reader what Tissier deems necessary for him to know concerning these matters. There is much of great interest in pneumotherapy and aerotherapy, and the mind of any practitioner will be broadened and strengthened by reading what the author has to say.

THE PRACTICAL APPLICATION OF THE RÖNTGEN RAYS IN THERAPEUTICS AND DIAGNOSIS. By WILLIAM ALLEN PUSEY, A.M., M.D., Professor of Dermatology in the University of Illinois; Member of the American Dermatological Association, and EUGENE WILSON CALDWELL, B.S., Director in the Edward N. Gibbs Laboratory, University and Bellevue Hospital Medical College, New York; Member of the Röntgen Society of London; Associate Member of the American Institute of Electrical Engineers. Philadelphia: W. B. Saunders & Company, 1903.

THIS work is divided into two parts; the first containing 215, the second 355 pages. The first, after an introduction, presents chapters on the essentials of an *x*-ray equipment; *x*-ray tubes; induction coils, interrupters and their management; static machines and their management. Fluoroscopy; radiography; the photographic materials and their manipulation; the choice of an *x*-ray outfit. While the apparatus is described with a master-hand, one feels a slight disappointment in the text relating to the use to which it is all put. The application to diagnosis is dwelt upon to a greater extent than the means of employment of the different forms of apparatus for the cure of disease. In part second many interesting questions are discussed. "The causes of the phenomena observed in tissues after exposure to *x*-rays," "What is the property in *x*-rays that affects tissues?" "How far should *x*-ray effects be carried," "Indications for the therapeutic use of *x*-rays," all this and many other topics are carefully considered. The author then gives his personal experience. The histories of numerous cases are given and the general conclusions to be drawn from them. The authors have conjointly added not a little to the literature of the subject, and as the contributions of each represent a certain proportion of actual original work done their words are entitled to an attentive aud ence.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles. By leading members of the medical profession throughout the world. Edited by A. O. J. KELLY, A.M., M.D., with the aid of various collaborators. Vol. I. Thirteenth Series. Philadelphia: J. B. Lippincott Company, 1903.

ON glancing over the contributors one sees that the same well-known men continue to work in the interest of this serial—Keen, Osler, Ballantyne, Finger, Wilcox, Satterthwaite are among the number. A review of the progress of medicine for the year by E. W. Watson presents the advances in a concise manner.

The special articles are by King on "Functional Reversion and Its Import in Medical Practice;" and by Ballantyne on "The General Principles of Embryology."

There are the usual number of illustrations, some showing interesting features of blastomyces and the dermatites it produces. The clinical reports, both medical and surgical, contain much new matter of practical interest and are well presented.

TRAVAUX DE CHIRURGIE. Anatomoclinique par HENRI HARTMANN, Professeur agrégé de la Faculté de Médecine avec la collaboration de: CUNÉO, ROGER, SOUPAULT, LUYS, LECÈNE, LEBOY, PRAT et DELAAGE. Voies Urinaires—Estomac. Paris: Georges Steinheils, 1903.

THIS is a collection of works whose scope is indicated by the title, emanating from the hospital service and laboratory, with clinical and statistical data, illustrated with one hundred and thirteen figures and cuts.

The first portion dealing with hospital arrangement and equipment will interest all hospital workers. Those interested in pathology will find many important reports. The surgeon will find well-illustrated methods of procedure, and he who looks for end results will find reports extending from the ward through the dead-house to the microscopical laboratory—but also reports of cures traced long after discharge of the patient. It is an unbound volume of 360 pages, on good paper. The contributors to both the genito-urinary part and to that dealing with stomach affections are to be congratulated on this result of their labors.

TRANSACTIONS OF THE AMERICAN RÖNTGEN RAY SOCIETY. Third Annual Meeting, Chicago, December 10 and 11, 1902. Louisville Courier-Journal Printing Co., 1903.

THERE are fourteen papers all on subjects of interest connected with radiography or radiotherapy. A list of about 250 members is given. The discussions are of much interest and many new points in the rapidly developing light-science are brought out.

PRACTICAL HANDBOOK OF THE PATHOLOGY OF THE SKIN. An Introduction to the Histology, Pathology, and Bacteriology of the Skin, with Special Reference to Technique. By J. M. H. MACLEOD, M.A., M.D., M.R.C.P., Assistant in the Dermatological Department, Charing Cross Hospital, Physician to the Skin Department Victoria Hospital for Children. With eight colored plates and thirty-two black and white plates. Philadelphia: J. Blakiston's Son & Co., 1903.

THIS is intended as a working book for students, and is based upon work and demonstrations in the laboratory. Not only will the student here find the patholigo-histology or the histopathology, but the flora of the skin, and the rules for obtaining results in individual investigation. The word "introduction" in the sub-title is well chosen, for it is not the intention to offer here a substitute for any complete work on skin pathology—did one exist. The book stands by itself and fills the place it occupies. Elementary anatomy is sufficiently entered upon to prepare a basis for the comprehension of subsequent chapters. If this should prove a stepping-stone to an anatomico-pathological nomenclature the work, done upon it will have been well spent. The author deserves praise for producing such a work, and all interested in the skin should become familiar with its subject matter.

THE CARE OF THE BABY: A Manual for Mothers and Nurses. By J. P. CROZIER GRIFFITH, M.D. Third edition. Philadelphia: W. B. Saunders & Co., 1903.

ACCORDING to the author, endeavor has been made in this volume to furnish a reliable guide for mothers anxious to inform themselves as to the best way of caring for their children in sickness and in health. The hygiene of pregnancy is first discussed, followed by a description of the characteristics of a healthy baby, together with the growth of its body and mind. Toilet, clothes, sleep, and feeding are all considered, much attention being naturally given to feeding. Under the head of sickness are considered such subjects as colic, prolapse of the bowel, hernia, worms, jaundice, croup, pneumonia, con-

vulsions, various deformities, and the infectious diseases.

MANUAL OF BACTERIOLOGY. By ROBERT MUIR, M.A., M.D., F.R.C.P.Ed., Professor of Pathology, University of Glasgow, and JAMES RITCHIE, M.A., M.D., B.Sc., Reader in Pathology, University of Oxford. American Edition from the third English Edition by Normana Mac Leod Harris, M.B. (Tor.), Associate in Bacteriology, the Johns Hopkins University, Baltimore. New York: The MacMillan Company, 1903.

THE American edition of this well-known manual is perhaps one of the best and most comprehensive, up-to-date handbooks for the student published in the English language. The treatment of the doubtful questions is to be commended. The investigations of each observer and the conclusions are stated with as little bias as possible. Where conclusions are not justified the facts are stated without advancing to a conclusion. Due prominence is also given to the recog nition of the facts which tend to show that many of the pathogenic organisms are members of a closely related group of bacteria. Several new illustrations and subjects have been added to this edition. These include a new chapter on the bacteriology of air, soil, and water. The chapter on immunity has been modified and extended, and consists now of a judicious statement of the experimentally ascertained data on this subject; the different abstruse conceptions of the nature and mechanism of this subject are skilfully handled, and unwarranted deductions from the many theories of immunity are avoided. An appendix furnishes a compact outline of the principal literature on the different subjects. This outline deals chiefly with the original works found in the foreign languages. Suzor's compilation on hydrophobia and a number of other references of value to the student who is not familiar with the foreign languages are omitted. The alterations and additions to the chapter on media, filtration of cultures and the miscellaneous methods, such as the use of the celloidin sacs for the study of the action of microorganisms when within the body, are very useful. The chapters on diagnosis, animal inoculations, the bacilli of the typhoid-colon group, and tetanus, also contain notable additions.

LE TRAITEMENT RATIONNEL DU DIABÈTE. Par M. le DOCTEUR A. LORAND, Médecin consultant aux eaux de Carlsbad. Paris: C. Naud, Éditeur, 1903.

THE various measures for the treatment of diabetes mellitus advocated in this attractively written essay are more or less those propounded by the modern German school. The author, a médecin consultant aux eaux de Carlbad, of course, gives preference to the mineral-water treatment at the spa, maintaining that it may not only favorably influence the pathological substratum of the disease, but also eventual complications, such as hepatic diseases, gastrointestinal catarrhs, etc. The author opines that as long as we do not know the real cause of diabetes, the mineral waters afford its most rational treatment.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. By GEORGE M. GOULD, M.D., and others. Volume on Medicine. 691 pages. Philadelphia, New York, London: W. B. Saunders & Company, 1903.

IT is not surprising that it has been found advantageous to continue the experiment of publishing this work in two volumes, a medical and a surgical, and of selling these separately. The ponderous tomes of former years were cumbersome and annoying to the reader, while those who were interested exclusively in either medicine or surgery naturally objected to the amount of space devoted to subjects which they did not care to study. The union of the departments of laryngology and otology under the editorship of Dr. D. Braden Kyle and Dr. George Fetterolf will be appreciated by many. In the department of general medicine, which occupies 248 pages, the infectious diseases, the conditions affecting the constitution of the blood and the diseases of the stomach are treated in a satisfactory manner. The next largest division, that of pathology and bacteriology, deals with numerous topics of importance, among the most interesting of which are intoxications, immunity, hæmolysis, the etiology of carcinoma and the general pathology of tumors. In the department of dermatology the novel and, for the present at least, absorbing topic of the therapeutic use of the *x*-ray and of the Finsen light receives due attention.

CHRONIC HEADACHE AND ITS TREATMENT BY MASSAGE. By GUSTAV NORSTROM, M.D., of the Faculty of Stockholm. New York and London: G. E. Steichert, 1903.

THE writer of this essay has had considerable experience in treating cases of migraine by massage, and his results have induced him to place his methods before the profession. Although we cannot accept without reserve his theoretical explanations of the causes of this obstinate malady, still the results which he has obtained compel attention to his method of treatment. To avoid misunderstanding of the classes of headache which have been cured, the author appends case-records and careful descriptions together with the outcome.

A SYSTEM OF CLINICAL MEDICINE, Dealing with the Diagnosis, Prognosis, and Treatment of Disease. For Students and Practitioners. By THOMAS D. SAVILL, M.D., London. Physician to the West End Hospital for Diseases of the Nervous System; Physician to St. John's Hospital for Diseases of the Skin, London; Formerly Medical Superintendent of the Paddington Infirmary; Medical Officer of the Paddington Work-House, and Post-Graduate Lecturer to the London Post-Graduate Association; Assistant Physician and Pathologist to the West London Hospital; Examiner in Medicine and Clinical Medicine in the University of Glasgow, and Medical Officer to the Royal Commission on Vaccination. Vol. I.: Local Diseases and Microbic Disorders. London: J. & A. Churchill, 7 Great Marlborough Street. Philadelphia: P. Blakiston's Son & Co., 1903.

THE first volume of this system, which will soon be completed by a second, approaches the subject of diagnosis by the way of symptomatology; in other words, the author means to help the student or the practitioner in his efforts to interpret the evidences of disordered health; and starting with some signs and symptoms, he may refer to this work and obtain valuable hints for further search. In addition to this index of symptoms a brief account of separate diseases, is added with their prognosis and treatment. We regret to notice, however, that no mention is made of the Brand bath in the treatment of typhoid fever, this being the accepted method in America, where a mortality of 10 per cent. in unselected hospital cases compares very favorably with the 15 to 20 per cent. which he quotes. However, the work accomplishes its purpose in being a friend in need when puzzling symptoms present themselves. It is a work quite unlike the usual textbook in teaching the reader to weigh his evidence for or against a certain diagnosis. Useful and practical charts and illustrations add to a text in itself well worth reading.

THE RÖNTGEN RAYS IN MEDICINE AND SURGERY. As an Aid in Diagnosis and as a Therapeutic Agent. By FRANCIS H. WILLIAMS, M.D. (Harv.), graduate of the Massachusetts Institute of Technology, Visiting Physician to the Boston City Hospital, etc. With 428 illustrations. Third edition, with enlarged appendix. New York: The Macmil ian Company, 1903.

THE first edition was reviewed in these columns in 1901—the second in 1902, and now it becomes our pleasure to look over a rewritten appendix in which is recorded 150 of the author's personal cases with a discussion of the therapeutic value of the Röntgen method. There are also twelve pages of bibliography, bringing the whole number of pages up to 757, or an addition of over 50 pages. To say that there has been advances made in the development of *x*-ray science is to put it mildly—both in the fields of diagnosis and therapy, as well as in apparatus and technique, improvements are constantly being made, and, to keep pace with them, necessitates frequent reconsideration. Professor Williams continues to reflect in his added pages the great amount of personal work and research of which his first edition gave abundant evidence, although nearly the whole of the new matter relates to the way as a therapeutic agent. Still the subject is of such growing importance that one feels that still more could be written upon it. Little or no change has been made in the body of the work.

UTERINE AND TUBAL GESTATION. By SAMUEL WYLLIS BANDLER, M.D. New York: William Wood & Co., 1903.

THE modern views concerning the processes antedating uterine gestation, the embedding of the ovum and the development of the embryo, are here presented in a clear and interesting manner, great prominence being given to the trophic influence of the ovary and the part played by its internal secretion in governing the development of the uterus, genitalia, and breasts, and in regulating menstruation. The origin of the syncitium is discussed at considerable length, and attention is called to the probability of the placenta being a gland possessed of great potentiality by reason of its secretion. The portion dealing with the etiology, histology, and usual course of ectopic gestation has already appeared in the *American Journal of Obstetrics*. The concluding chapter describes chorioma, perhaps better known under the name of deciduoma malignum. All of the subjects covered are admirably presented, and in this the author has been materially aided by the introduction of ninety-three illustrations.

### SECTION ON SURGERY.

*Stated Meeting, Held May 11, 1903.*

ROBERT T. MORRIS, M.D., CHAIRMAN.

**A Consideration of General Anæsthesia, with a Presentation of Instruments.**—Dr. FREDERIC GRIFFITH presented this paper. He said that anæsthesia was produced by a direct action upon the cerebrospinal nerve centers. The indications for an anæsthetic were to relieve the pain of an operation or of childbirth; to overcome the general spasm of strychnine poisoning, traumatic tetanus, puerperal infection and uræmic convulsions; the muscular spasm in fractures and dislocations, and the passage of gallstones and renal calculi.

**Selection.**—In selecting anæsthetic, the ether should be the one of choice when the administrator was inexperienced; also in atheroma and organic heart disease. As a rule, loud cardiac murmurs denoted power in the cardiac muscle, and were, therefore, of better omen than low murmurs, which pointed rather to poor compensation. Chloroform should be selected for brain and eye surgery upon persons having either lung or kidney disease. Nitrous oxide was useful as a preliminary to other general anæsthetics in cases of atheroma or aneurysm, and when it was desired to restore motion in ankylosed joints. Bromide of ethyl was very prompt in its action, and did not depress the heart.

**Administration.**—It should be remembered that no two individuals took an anæsthetic alike, and that the skilful anæsthetist was one who recognized this fact and acted accordingly. Ether might be more carelessly given than chloroform without ill effect. The anæsthetist was often more important than the operator, and at all times the operator should keep him well informed as to the progress of his work. Twenty-four hours before the administration of an anæsthetic the patient's bowels should be flushed out by giving calomel, one-fourth of a grain, every twenty minutes until two grains had been taken, and following this by a dose of Epsom salts. A high soap-and-water enema should be given on the morning of the day fixed for the operation. Of course, the patient's heart, lung, and urine should be carefully examined. At the time of the operation all superfluous garments should be removed, remembering, however, carefully to conserve the body heat by blanketing. Anything loose in the mouth should be removed, and note should be taken of the dental work. The patient's eyes should be protected by gauze or a towel, and, following the suggestion of Bodine, he should be instructed to listen to the anæsthetist's voice and keep the hands tightly clasped. There should be no conversation or other noise in the room while giving the anæsthetic to induce narcosis. Besides the inhaler, the anæsthetist should have a wooden screw, a mouth-gag, tongue forceps, curved needle, swabs on sticks or forceps, and a sterile hypodermic syringe. When a hypodermic injection was required the application of tincture of iodine would sterilize the skin for the puncture. The speaker said that he personally made use of a single-ear stethoscope, placed over the precordium, in order to keep informed of the condition of the heart. Strychnine, morphine, and atropine should also be near at hand. The collection of mucus in the throat was not necessarily due to poor anæsthetization. Because of the complications liable to arise from psychical erotism it should be the rule never to anæsthetize a female when unattended. Vomiting in an early stage was often due to the use of too little ether, but later on was usually caused by giving too much ether. When the latter was the case, the ether should be stopped, the patient's head turned to one side, the tongue and jaw brought forward and the mouth cleaned out. When using ether with the bag inhaler, the addition of fresh ether often caused vomiting; the remedy was to have a sufficient supply of ether. More ether was required in summer than in winter because of the greater evaporation.

**Poisoning.**—Poisoning due to idiosyncrasy was rare, and an overdose of ether was likewise rare. Lividity and pallor of the face, dark blood and a thready pulse indicated that the ether should be stopped, and the patient be given more air, or perhaps stimulated by the application of wet towels to the chest or by the use of artificial respiration, rubbing with ether, or the inhalation of ammonia or oxygen. For hypodermic use one should give $\frac{1}{15}$ of a grain of strychnine or $\frac{1}{150}$ of a grain to $\frac{1}{100}$ of a grain of atropine sulphate. The author was of the opinion that nitrite of amyl was useless.

**A New Inhaler.**—Dr. GRIFFITH then presented his inhaler. This was designed to meet the demand for a single instrument for the safe combination of anæsthetics. It consisted of a metallic face piece which would not collapse during respiration, and which fitted closely to the patient's face by means of a pneumatic cushion. By means of a single valve the gas was delivered in increasing proportions until, without a struggle or any sign of apparent discomfort, the patient was thoroughly anæsthetized in a period of time varying from thirty seconds to three minutes. A supply of fresh air was constantly admitted to the mixing chamber in any desired quantity by means of slide openings at the top of the receptacle for liquid. Although ether was commonly used in combination with nitrous oxide gas, chloroform could be just as readily employed. Should the supply of gas run short before the patient was completely anæsthetized, re-breathing was provided for by the use of a stopcock fitted to the reservoir gas-bag.

**Modification of Esmarch's Chloroform Dropper Aimed to Secure Reliable Dropping.**—Dr. VICTOR C. PEDERSEN read this paper. He said that he wished to deal with chlorofrom narcosis without claiming any advantage of one anæsthetic over another, but rather the right use of all. Chloroform was the immediate cause of death in a great number of cases, but ether killed nearly as many by producing kidney disease or pneumonia. Chloroform and ether were classed with the stimulants and depressants, the action of one or the other depending upon the dosage. In administering chloroform several points had to be borne in mind. In the first place, a proper mask must be used, for in giving chloroform it was necessary to give it with 95 to 97 per cent. of air. For practical purposes any metal frame would answer, but it should be covered with from two to four thicknesses of gauze, the redundant edges of the latter being turned into the hollow of the mask. In the next place, a suitable chloroform dropper was very important. The ordinary Esmarch dropper acted well when the glass stopper was well ground, but when this was not the case two or more drops would flow out just when they should not. By having the opening at the mouth of the dropper at a right angle to the tube this excessive dropping would be prevented. The diameter of the chloroform tube should be so proportioned as to allow half air and half chloroform. Chloroform should be literally given drop by drop, and in case coughing occurred it should be stopped momentarily. The administration of chloroform should not be hurried, and at least five minutes should be taken to induce narcosis. No stertorous breathing should occur. The pulse should be from 75 to 80 per minute, compressible and slightly increased. If the pulse rate rose to 90 he would personally change from chloroform to ether. The condition of the capillary circulation constituted one of the most valuable indications as to the reaction of the nervous system, though the condition of the heart and the color of the blood were important. Feeble breathing was not always a sign of great danger. Pallor of the face and

nose generally meant beginning shock, though pallor alone might be followed by some respiratory difficulty. The response of the eye to light should never be entirely abolished. A widely dilated pupil meant slight narcosis When the pupil did not react to light for one or two minutes it was an indication that the chlorofrom narcosis was profound, and it should not be carried further. It was important to have the room in which the anæsthesia was induced perfectly quiet and brightly lighted. In certain circulatory conditions, as for example those connected with organic disease of the heart, he favored the use of a combination of ether and chloroform, but in inorganic heart disease and anæmia he used chloroform alone. When there was some respiratory affection ether alone was contraindicated, and chloroform, or a combination of chloroform and ether, should be selected. Nervous patients did not take chloroform well. The operations in which the anæsthetic had to be stopped for a few minutes at a time, *e. g.* operations on hare lip, adenoids and tonsils, ether should be selected because the the narcosis would last longer.

**A New Nitrous Oxide and Ether Inhaler.**—Dr. NATHAN W. GREEN presented this inhaler. He said there was a tendency at the present time to make use of the combination of nitrous oxide and ether, and with this inhaler the comfort of the patient was increased while the time of anæsthetization was reduced. The apparatus was simple and compact, and could be held in one hand and worked with the fingers of the same hand. It consisted of a metallic cone with three valves on one side, one valve for the air, another for the nitrous oxide, and a third for the ether. These valves were arranged and operated after the manner of the stops of a cornet, and without any motion which would attract the patient's attention.

Dr. J. T. GWATHMEY exhibited another inhaler in which the upper chamber of the Bennett inhaler had been discarded, and that instrument further simplified.

Dr. MARTIN W. WARE, referring to ether pneumonia, so-called, said that at the last meeting of the British Association of Anæsthetists the consensus of opinion was in favor of considering this an aspiration pneumonia. The fatalities from nitrous oxide gas had been more numerous during the last ten years than in the two decades and a half preceding. He had used nitrous oxide gas anæsthesia in operations of minor surgery, and had given it five thousand times before witnessing a crisis or fatality; then, in connection with an operation for the incision of a bubo, the patient became cyanosed, but was rallied after stopping the gas. One reason nitrous oxide gas was not more generally used by the profession was the large quantity of the gas required, and the expensiveness of the inhaler. Dr. Ware said he had used ethyl chloride anæsthesia from 1,000 to 1,200 times, and it possessed certain advantages over nitrous oxide. The expense was not much below that of the latter, and it was not quite so safe, but the patient was more relaxed and never became cyanosed. A special mask was necessary for its administration. Its mortality was said to be one in twenty thousand. Ethyl chloride was superior to ethyl bromide because with the latter cyanosis was marked, and the mortality was greater.

Dr. PEDERSEN closed the discussion. He said that up to the present time he had not had any cases of ether pneumonia, and this good record he attributed to the fact that the ether mask was always boiled and the patient's mouth washed out with peroxide of hydrogen or some other antiseptic solution. This precaution seemed a proper one when bacteriologists told us of the frequent presence of pneumococci and other organisms in the mouth. He had only used ethyl chloride once, in a vigorous colored person, but as the patient became rigid and cyanotic, and presented a somewhat alarming condition, he had not felt inclined to give this agent a further trial.

## NEW YORK COUNTY MEDICAL ASSOCIATION.

*Stated Meeting, Held May 18, 1903.*

ALEXANDER LAMBERT, M.D., PRESIDENT.

**Carcinoma of the Rectum and Uterus.**—Dr. FREDERICK HOLME WIGGIN presented several specimens. The first one had been removed from a woman, fifty years of age, who had ceased menstruating three years before. Three months before coming under observation the menstrual flow had apparently returned. The attending physician thought the mass projecting from the cervix was a polypus, and could not be a cancer because it was so soft. After operation the specimen was submitted to the pathologist, Dr. F. M. Jeffries, who reported that it was a peculiarly malignant type of carcinoma. The specimen was presented in order to emphasize the fact that the absence of induration did not necessarily exclude malignancy.

The second specimen had been removed by operation from a woman who had been operated upon about six months previously for a scirrhus of the breast. She died shortly after operation with evidences of acute suppression of the urine. The pathologist reported the tumor to be a carcinoma invading the body of the uterus.

The third specimen was a carcinoma of the rectum involving the posterior vaginal wall and the vulva, and more than one-half of the labium majus on each side. The disease was removed by operation with a very satisfactory result.

**Sarcoma of the Neck.**—The next specimen was a large mixed-cell sarcoma of the neck. At the operation it was found that the external carotid artery was involved in the growth, but after ligating the common carotid it was comparatively easy to extirpate it. The operation had been done a week before, and in spite of the apparently desperate nature of the case at the time of the operation the patient was doing well. When the patient had sufficiently recovered he would be advised to submit to a course of *x*-ray treatment.

**Large Mass of Varicose Veins.**—The last specimen presented was a very large mass of varicose veins, which had extended from the ankle to above the knee, and which had been successfully removed by operation.

**Etiology, Serum Diagnosis, and Serumtherapy of Dysentery.**—Dr. W. H. PARK presented this paper. The speaker said that for many years amœbæ had been found in the stools of tropical and chronic dysenteries, and these stools produced in animals symptoms resembling those of dysentery. It was almost certain that tropical dysentery and some of the dysentery occurring here in temperate regions were partly at least dependent upon the presence of these amœbæ. Until the work of Shiga very little had been added to our knowledge of this disease. Some observers were of the opinion that many forms of dysentery were due to colon bacilli of special virulence, and this seemed to be perfectly possible. In 1897 and 1898 Shiga, working in Kitasato's laboratory, thought he would not only examine the stools but would apply a serum test. He found in practically every case examined a bacillus, which up to that time had not been clearly defined. These bacilli for practical purposes might be considered as belonging to the colon group, although they differed in certain important particulars. These bacilli were found from the first days of the disease up to convalescence in all of the acute cases, and they were not present in the normal stools of children and adults except here and there in localities in which an epidemic was raging, and then just prior to the onset of the disease in these individuals. Subsequently a number of investigators went from the Johns Hopkins University to Manila to study dysentery. They found that although in a great number of the worst cases the amœbæ appeared to be the cause, there were many other cases of acute dysentery, and some of subacute or chronic dysentery in which no amœbæ were found. They then examined for the Shiga bacillus, and thought they found this bacillus in many of the cases in

which the amœbæ were absent. Coming back to this country, Flexner set several of his students, particularly Vedder, Duval, and Bassett, to work upon this subject. Last year it was found that the ordinary type of summer diarrhœa in Baltimore was a mixed type of diarrhœa and dysentery, and that in these cases the Shiga bacilli were uniformly present. Dr. Park said that he had then undertaken to investigate the infantile diarrhœas occurring in New York City last September. On inquiry he had learned from Dr. Frank W. Shipman that there had been an epidemic of dysentery in Mount Vernon and Tuckahoe, which was very much like that observed in Japan. In the bacteriological study of these cases unexpected difficulties were encountered. At length it was discovered that the bacilli in different localities had special cultural characteristics. The bacilli were most abundant in the early days of the disease, but they had been known to persist for six weeks. These groups of bacilli were found to differ in serum reaction, cultural tests, and bactericidal properties. In the vicinity of New York City the dysentery was associated with an indol or colon type of bacillus. Further study showed that in chronic intestinal disorders in human beings one could not absolutely rely upon the serum reaction. In little children they never obtained a reaction above one in ten if they were free from intestinal disease and otherwise healthy. In children under four years of age one was not apt to find the agglutinins of these bacilli. In adults it was learned that any reaction under one in twenty was not safe to rely upon. If there was any intestinal disease, such as appendicitis, chronic diarrhœa or chronic dysentery, the reaction became useless. In the Mount Vernon and Tuckahoe cases it was found that when the disease was mild the reaction was not usually obtained in over one in ten; in the moderate cases it was present in one in thirty or forty, and in the severe cases in one in fifty or one hundred. The subject was to be very thoroughly studied this summer. He was personally very skeptical of the use of the serum for therapeutic purposes outside of the diphtheria antitoxin or of the tetanus antitoxin for immunization. Both Shiga and Dr. Kinyoun had expressed the opinion that when the serum treatment was employed quite early in dysentery all of the symptoms abated so promptly that there seemed to be no question about the relation of cause and effect. It should be remembered that dysentery was usually a comparatively local disease, being confined, for the most part, to the lower portion of the rectum. The serum treatment had been employed in this city in about fifteen hospital cases with no very striking results, but it was quite possible in these cases that the results were interfered with by mixed infections. The Health Department would provide this serum this summer for those who would carefully observe its effect and report upon the same.

**Clinical Observations on an Epidemic of Dysentery.**—Dr. Frank W. Shipman of Mount Vernon read this paper. He said that the epidemic referred to occurred in the valley of the Bronx River, extending for a distance of eight miles north and south and one mile in width, the center of activity being Mount Vernon, N. Y. The epidemic lasted from June to September, and in Mount Vernon this disease showed no respect for persons and did not spread through the intercommunication of any particular class. There was abundant evidence that the outbreak was not due to infected water or milk. There were five different water supplies, and the sources of milk were equally varied. Prodromal symptoms were not usually present, and when they were they lasted but a short time. Vomiting when present occurred during the first few days. The stools consisted at first of fecal matter, and in twenty-four hours changed to the characteristic dysenteric stool of blood mucus. At first, the blood was of a bright red color, but later it became dark. Very soon the rectal tenesmus became distressingly severe, and the disease was at its height in forty-eight hours, the pulse being about 120 and the temperature 102°F., the abdomen retracted and the patient greatly prostrated. In some of the severer cases toxic symptoms supervened, as evidenced by subnormal temperature and collapse. The pathological process consisted of an inflammation of the mucous coat of the colon with ulceration and more or less hemorrhage. The treatment generally followed was an initial dose of calomel or castor oil followed by salines. Occasional irrigations of the bowel were employed. Large and repeated doses of opium were sometimes required to control the severe tenesmus. The greatest relief was afforded by the external application of heat or the irrigation of the bowel with warm water. The usual antiseptics were prescribed, but apparently without benefit.

**Surgical Treatment of Dysentery.**—Dr. Charles L. Gibson read this paper. He said that, according to his experience, severe cases of dysentery usually involved the greater part of the large intestine. The surgical relief of colitis consisted in the establishment of an artificial anus to give physiological rest of the affected part and allow of its proper cleansing with or without antiseptics. In 1900 he had devised an operation for the relief of the condition, which was briefly as follows: A small intermuscular incision was made over the caput coli and a tube was introduced and unfolded in the cæcal wall in such a way as to guarantee against leakage. After the tube had been in place a week it was removed and the artificial valve then became operative. The tube should be introduced from two to four times a day and the colon flushed out with normal saline solution and with nitrate of silver solutions of gradually increasing strength. The opening would quickly close on ceasing to insert the tube. The treatment involved only a ten days' stay in bed and no subsequent and severe operation. With the operation just described the results had so far been very satisfactory.

Dr. John W. Smith of Tuckahoe, N. Y., presented a few notes of the epidemic as seen by him. It began in Tuckahoe about the middle of July, attained its height by the middle of August and diminished rapidly in September, so that there were no more cases by October 1. The first case occurred in a filthy tenement-house situated near a pool of stagnant water. The drinking water used by the Italians in this tenement was taken from a well situated between the house and the stagnant water. New cases rapidly developed, for the most part within a radius of one thousand feet. The evil effects of overcrowding were evident here. The speaker believed with Dr. Shipman that dysentery should be recognized by our boards of health, and that compulsory notification of it should be required. It was worthy of note that recovery uniformly took place unless the vitality was manifestly below the normal. Sulphate of magnesia or castor oil was given at the outset, and was repeated when there was not a proper evacuation of the small bowel. Calomel, opium, and ipecac were given to adults, but this medication did not seem to be of benefit in children. Lavage with normal salt-solution was used.

Dr. O. L. Austin of Tuckahoe said that he saw 234 cases during this epidemic of which he had kept records. Diarrhœa with bloody stools was present in every case. In 85 per cent. diarrhœa was the first symptom; in only 3 per cent. was it developed as late as thirty-six hours after the onset of the pain, vomiting, and fever. The number of stools varied greatly in different cases and in the same individual at different times. The average number of stools was eight for the first day, fifteen for the next six or seven days, and then three or four a day. A marked change in the stools rarely took place until near the close of the disease, a reliable indication of approaching convalescence being the presence of some solid fecal matter. Blood appeared early, at first as a few bright specks, after which the amount increased rapidly. If the quantity of blood was not great the stools were black

and tarpy. As a rule, there was very little odor from the dejecta. Next to diarrhœa tenesmus was the most striking intestinal symptom, though in fourteen cases it was not present, and in thirty others it was only slight. Constipation was common during convalescence. Fecal incontinence was present in twelve cases, young children, and occurred only after the disease had lasted some days and the exhaustion had become marked. Abdominal pain was present in every case, and sometimes was out of proportion to the other symptoms. During the first day it was colicky in character, but later on a paroxysm of pain often immediately preceded the stool. The pain soon became localized and diminished rapidly after the disease had reached its height. Tenderness over the colon was uniformly present, and persisted after the other symptoms had subsided. In infants, vomiting was the rule. It occurred in 16 per cent. of the other cases. The temperature was relatively low, being between 99° and 102° F. even in severe cases. In eleven instances, all presenting toxic symptoms, the temperature was subnormal. The pulse in the adults was usually between 125 and 130, and in children under four years of age, 140. This rapid and feeble pulse developed quite early in the disease. Marked prostration appeared early, was a prominent feature from the outset and was out of proportion to the other symptoms. Emaciation in children was extremely rapid, being more marked in a few days than was usually observed in three weeks of a severe gastroenteritis. In four cases there was prolapsus ani; in seven there were very sluggish bedsores; in two an endocarditis developed; in thirteen cases bronchitis occurred, while pneumonia was not observed at all. The average duration of the disease was five days for the mild cases, and four weeks for the more severe ones. The mortality among his cases was about 2 per cent.

Dr. Morris Manges said that the type of the disease presented was certainly very little known among practitioners in this vicinity. He had had a personal experience with four cases of chronic dysentery treated surgically. Anyone who was familiar with these cases knew how pitiable was their condition and how welcome would be almost any method that held out hope of relief. He knew of one case of chronic colitis upon which colostomy had been performed by Dr. Gerster, and death had resulted in twenty-four hours. He knew of two other cases that had died a longer time after the operation, and of one that had been cured. From what he had seen it was evident that these patients were very poor subjects for surgical operation, although the results might be better if the patients came under the surgeon's care earlier in the disease. Boas had recently reported a case in which an artificial anus had been made, and it had taken a whole year to effect a cure. Ewald had reported a case upon which he had operated six years before, and upon which Trendelenburg was compelled to operate subsequently before it was cured. It was noted, however, by these observers that although a cure was not effected the patients improved very greatly under surgical treatment. He thought in many of these cases the valve-like method suggested by Dr. Gibson would not suffice, and that the ordinary artificial anus would be required.

Dr. Frederick Holme Wiggin reported a case treated surgically in the City Hospital. The patient had contracted dysentery in the Philippines, and on examination of the stools amœbæ were found. The abdomen was opened, the appendix brought to the surface and fastened by a few stitches. For the first week large colonic irrigations were given. Saline solution was used at first, and subsequently a weak solution of permanganate of potassium. The man recovered from the dysentery, and some time afterward the appendix was removed, and he eventually left the hospital entirely well.

## AMERICAN NEUROLOGICAL ASSOCIATION.

*Twenty-ninth Annual Meeting, Held at Washington, D. C., May 12, 13, and 14, 1903.*

FIRST DAY—TUESDAY, MAY 12.

Dr. J. W. Putnam of Buffalo, President, in the Chair.

**Address of President.**—The Congress of American Physicians was founded because the interdependence of the different branches of medicine was recognized by the master minds of the profession. The time had come when specialists needed to broaden their interests and enlarge their views of the field of medicine. Specialism is so engrossing that its devotees are in danger of becoming narrow in their interests and their activities.

The range of diseases we are called upon to treat is so large and so varied that it would seem impossible for us to become narrow.

The chronic cases of paralysis with deformities from various cerebral spinal and peripheral causes, form a large and hitherto hopeless class. For years those afflicted with diplegia, hemiplegia, and spastic paraplegia have sought medical aid in vain. Tendon transplantation and the principles which govern the operation should find a place in our chapters on treatment. It should be taught to the student from the neurological standpoint as well as from the surgical. We have long ago made common cause with the surgeon in cerebral and spinal operations; let us extend it to the domain of surgery of the neuro-muscle machine. To the surgeon belongs the technique. To us belongs the duty of selecting cases for operations and of enlarging its field of usefulness. The after-care of the patient is as important as the surgical. The operation must be followed by an education, both mental and physical, which we must direct. It is only through coöperation that the best results will be obtained.

Hitherto the relation of neurology to obstetrics has not been sufficiently appreciated nor emphasized. The effect of prolonged labor upon the child is being studied and requires much more careful investigation in order to determine the effect of cranial birth injuries upon the brain. The obligation rests with us to sound the note of warning in season and out of season that epilepsy is in a large number of cases due to cranial birth lesions. The lesson must be so impressed that it will be a rule with accoucheurs to examine the head for fractures or undue depression after severe labor. When this practice has become a rule, and the cranial injuries are treated early and carefully, we may see as a result a diminution in the number of cases of epilepsy, idiocy, and cerebral birth palsies.

**The Sign of the Orbicularis.**—This was the title of a paper by Dr. George W. Jacoby of New York. The sign of the orbicularis is a symptom which consists of the inability of a hemiplegic voluntarily to close the eye upon the paralyzed side except in conjunction with the other eye. Thus, in cases of hemiplegia the temporofacial branch of the facial nerve is often so slightly affected as to lead to doubt whether the upper facial territory is involved at all. If in such a case the hemiplegic be asked to close both eyes together, he is able to do so without difficulty. He is also able to close the eye upon the sound side while keeping the eye upon the affected side open, but he is unable to reverse this procedure and close the eye upon the paralyzed side while keeping that upon the unaffected side open. This sign has hitherto been supposed to occur in central paralysis only. It was claimed by Jacoby that in many cases of peripheral paralysis this sign is present, and can be found if sought for at the proper time. These observations formed the basis for the following conclusions: (1) The statement of Board that the sign is invariably lacking in peripheral facial paralysis and is therefore a distinguishing mark of central affection, is incorrect. (2) The presence of the sign in peripheral paralysis is further proof of the existence of commissural fibers between the nuclei of the seventh nerves. (3) The

sign is of clinical value in so far as its presence in peripheral paralysis shows that complete recovery has not yet occurred. (4) The secondary over-action in the orbicularis palpebrarum which is late in appearance, and always coincides with some recovery in power, does not occur in those cases in which the sign having been present has passed away.

Dr. G. L. WALTON of Boston thought it important to bear in mind that unilateral control of the lid movements differs on the two sides in health. More individuals can close the left eye alone than can close the right eye alone. This may be due to the better education of the left cerebral hemisphere, for the education consists in learning to hold one eye open, not to close one eye.

Dr. JACOBY said that the independent closure of each eye was entirely acquired, and that in countries where a great many pursuits are followed which necessitates the independent closure of the eyes, is much greater than in countries where those pursuits do not exist.

**The Achilles Reflex and the Front-Tap.**—This was the title of a conjoint paper by Drs. GEORGE L. WALTON and W. E. PAUL of Boston. It was stated that the Achilles-jerk has been extensively studied, but has not taken the place it should as a routine test of equal importance with the knee-jerk; the front-tap has not been extensively studied. The Achilles-jerk is practically of equal constancy with the knee-jerk, is more uniform in excursion and requires less skill than the knee-jerk. In tabes, the writers have found it absent more constantly than the knee-jerk. The kneeling posture is preferable in most cases. In 500 cases without central nervous disease this reflex was wanting on both sides in only one instance; on one side, in four. Sluggishness of the tendon reflexes in health may be due to prior toxic affection, as diphtheria. In epilepsy the Achilles-reflex and knee-jerk are active except during the attack. The Achilles-jerk is sometimes absent in osteocarthritis with sciatic pain. The writers explain the front tap as allied to ankle-clonus though not of its sinister import. The foot being dorsally flexed by the examiner puts the calf muscles on the stretch, and the tap upon the tibialis anticus, by tending to dorsally flex the foot still further, suffices to produce contraction of the calf muscles. This reflex was present in 40 per cent. of 500 individuals healthy or suffering from no nervous disease. In epilepsy, hysteria, neurasthenia, and other neuroses it was found present in about 75 per cent. It was never found present in tabes or other hypotonic affections.

**The Reflexes in Long-distance Runners.**—This was a paper by Drs. PHILIP C. KNAPP and J. J. THOMAS of Boston. They had made a comparative study of the knee-jerk and allied reflexes in the participants in the "Marathon" run of twenty-four miles taken before and after the run, showing the influence of severe physical exertion combined with mental excitement upon the reflexes. In some cases the knee-jerks were lost. In all, the plantar reflexes were more or less exaggerated.

These two papers were discussed together.

Dr. F. W. LANGDON of Cincinnati said he had made it a rule to test the ankle-jerk in tabes and other conditions. He had not found it uniformly absent in tabes, but had seen a number of cases of tabes with the knee-jerk and ankle-jerk preserved. In sciatic neuritis it is either markedly diminished or absent on the affected side.

Dr. JOSEPH COLLINS of New York found the ankle-jerk more frequently absent in tabes than the knee-jerk, the ankle-jerk sometimes disappearing earlier than the knee-jerk, which is a more constant manifestation. In the depressed or vasomotor type of neurasthenia he had found the "front tap contraction" diminished or absent in a large proportion of cases.

Dr. C. L. DANA of New York said that the ankle-jerk was absent in one-half the cases of so-called sciatica. It is not so easy to test the ankle-jerk as Dr. Walton has stated. It may also be elicited by reënforcement.

Dr. H. T. PATRICK of Chicago had been in the habit of testing the ankle-jerk in every case, and had noted a difference in the two sides more frequently than in the case of the knee-jerk. In some cases of tabes, the knee-jerk disappears first. In others, the ankle-jerk is the first to disappear.

Dr. PHILIP ZENNER of Cincinnati had observed a number of instances in elderly individuals in whom the ankle-jerk was absent. The nervous system appeared to be normal.

Dr. JACOBY said that in cases of tabes when the ankle-jerk is present a careful examination will show that the knee-jerk is also present, but that we may have the ankle-jerk absent and the knee-jerk present. The loss of the ankle-jerk usually precedes the loss of the knee-jerk.

Dr. KNAPP agreed with Dr. Walton in his conclusions regarding the ankle-jerk. He thought that the front-tap contraction seemed more or less associated with ankle-clonus. It has considerable significance as an indication of exaggeration of the tendon reflexes.

Dr. WALTON, in closing the discussion, said that probably those cases of sciatica with loss of ankle-jerk result from pressure on the nerve-trunks by the products of osteoarthritis of the spine, or possibly from neuritis. He had been surprised to find how persistent the ankle-jerk and the knee-jerk are in advancing age. There is no invariable rule regarding the priority of disappearance of the knee-jerk or ankle-jerk in tabes.

(All of the speakers agreed that the best method of obtaining the ankle-jerk was to have the patient in a comfortable kneeling position on a chair during the examination).

**Primary Sarcomatosis of the Central Nervous System.**—This was the title of a paper and the report of cases by Drs. WM. G. SPILLER and WM. F. HENDRICKSON of Philadelphia. In the first case the symptoms were those of brain tumor and of transverse lesion of the thoracic cord. Multiple sarcomata of the brain and spinal cord were found. In the second case the symptoms were those of cerebellar tumor, and operation was done. Many tumors, some large and some small, were found in the membranes and nerve-roots of the brain and spinal cord. In the third case the symptoms were those of a transverse lesion of the thoracic cord. A primary sarcoma of the spinal cord substance was found. Attention was called to the comparatively few symptoms present in Case 2, notwithstanding the extensive sarcomatosis. The resemblance to syphilis of the nervous system was also discussed. The occurrence of a tumor in the cerebello-pontile angle in many of these cases of sarcomatosis was mentioned, and the question of operation was raised. The importance of the recognition of sarcomatosis of the central nervous system was emphasized, especially as regards surgical intervention when the symptoms seem to indicate that only one tumor is present, as in Case 2.

**Spinal-cord Tumor Treated by Operation.**—Drs. JAMES J. PUTNAM and J. W. ELLIOT of Boston reported three cases of tumor involving the spinal membranes.

The first case was noteworthy because the tumor, which proved to be a sarcoma, involved the axis and atlas and had caused a generalized paralysis, together with marked impairment of the respiration.

The growth was not sharply delimited, but was removed, so far as possible, with the curette.

In spite of the serious nature of the disease the patient has improved so much that he is now keeping a small store.

Three years have now elapsed and there has been no recurrence of the disease.

In the second case, a new growth, which was likewise of sarcomatous character, formed a collar about the spinal cord and dura at the junction of the cervical and dorsal region. The removal was successfully accom-

plished, but the respiration became much impaired even during the operation. The next day the temperature began to rise and continued to mount rapidly until the patient's death on the second day.

This result recalled one of the rarer effects of spinal injury. No cause could be ascertained for it, unless it were that the dura was punctured slightly at the time of operation.

In the third case, which was one of secondary cancer, involving the vertebral column and membranes in the lower dorsal region, the operation had been undertaken distinctly for the relief of pain. The growth was discovered at the expected point and was removed so far as possible. The main point of the operation, however, consisted in the cutting of two spinal nerve-roots, which were involved in the tumor. As a result of this, the patient's condition was considerably ameliorated for a number of weeks, at the end of which time she was seized with convulsions and other signs of involvement of the brain, and died shortly afterward.

The last two papers were discussed together.

Dr. W. A. Bullard of Boston said that where we have to deal with the dura and the membranes of the spinal cord, laminectomies are not so harmless as one might suppose. In a recent case in which there was anterior dislocation of the fourth cervical verterbræ, laminectomy was done for pachymeningitis. The operation was successful surgically, but after forty-eight hours fever developed, and the patient died without apparent cause. He had seen the same result in other cases.

Dr. B. Sachs of New York believed that cases of general sarcomatosis are not so very rare. He had seen a case of multiple gliosarcoma in a child which ran a rapid course. In a man forty years of age, a tumor appeared on the frontal bone. On account of the multiplicity of symptoms the question was raised whether the disease was of syphilitic origin or sarcomatosis. The case terminated fatally, and proved to be a general sarcomatosis. He did not think special credit was due any one for making a correct localization for spinal cord or brain disease. The question of greater importance is to be able to determine before operation the character of the morbid process. In this connection, he cited a case in which all the signs of spinal-cord tumor were present, and an accurate localization recorded. Upon operation no growth was discovered. The patient died two weeks later. Macroscopically the cord appeared normal, but on microscopical examination a number of small tubercles were found in the dorsal and sacral roots with tuberculous infiltration of the cord.

Dr. H.T. Patrick of Chicago reported a case in which a tumor apparently sprang from the auditory nerve. The patient had gradually become quite deaf, this having been preceded by rhythmic tinnitus. The tumor was very easily removed, and proved to be an osteosarcoma of the petrous portion of the temporal bone, the deafness being due to protrusion of the growth into the internal ear. Death took place shortly after the operation.

Dr. Wm. C. Krauss of Buffalo referred to a successful case of removal of a spinal-cord tumor from the cervical region which he reported at last years' meeting of the association. Five months after the operation the patient died. The tumor was a small round-cell sarcoma.

Dr. M. A. Starr of New York asked Dr. Putnam if there had been any respiratory difficulty during the operation for tumor of the axis. In a case of fracture of the third cervical verterbra there were distinct pressure symptoms upon the cord. During etherization he stopped breathing. Artificial respiration was kept up. The second time, chloroform being used, all voluntary respiration ceased. With artificial respiration during the entire operation a considerable amount of bony callus was removed with the relief of pressure. The boy is now in perfect health at the end of five years. He thought Dr. Spiller has done great service in presenting the subject of multiple tumors of the brain and spinal cord. He referred to a case in which a tumor was localized in the motor zone, but at the operation no tumor was discovered. The patient was tuberculous and lived four months. At the autopsy eight tumors were found scattered around in different areas of the brain, none being located in the motor zone. One tumor had absorbed about one-half of one lobe of the cerebellum for which no symptoms at all had been present. The medullo-pontal junction is a favorite point for tumors. He had seen five cases. In all of those operated upon death resulted. Sudden death is very common in all brain tumors. He recently had two cases of tumor of the cerebellum. Both patients died suddenly.

Dr. G. J. Preston of Baltimore spoke of malignant cerebral tumor following disease in the breast, and reported a case in which the growth was localized in the parietal region, but was found in the ponto-bulbar region.

Dr. Collins referred to a case of sarcoma in the abdomen which terminated fatally. Multiple sarcomata were found in the brain and spinal cord.

Dr. C. L. Dana said that a few years ago he saw a patient in whom a sarcoma was successfuly removed from the cervical portion of the cord. Improvement followed. In a case of removal of a tumor from the pontine angle the patient died. He called attention to the fact that cerebral softening from arterial fibrosis sometimes stimulates brain tumor exquisitely.

**Brain Tumor.**—Dr. C. Eugene Riggs of St. Paul reported two cases of brain tumor (endothelioma) with characteristic symptoms of involvement of the left motor area. Both were submitted to operation and terminated fatally.

Dr. Charles K. Mills of Philadelphia spoke at length in regard to operation for brain tumors. He believed that the cause of failure in operation was often due to imperfect methods of procedure. In Philadelphia they had gradually evolved more and more rapid methods of operation. He recommended the large osteoplastic flap made by a combination of the use of the trephine with the dental engine. He considered this method of valus on account of the saving of time. In the last operation, the skull was opened in eight minutes without shock. He believed strongly in operation for brain tumors in the majority of cases, if they were at all accessible.

Dr. Starr said that the best method to use was Doyen's electrical apparatus, and he considered it as rapid as the method spoken of by Dr. Mills. By this means it was possible to cut through the skull in fifteen seconds. He cosidered this a great improvement upon the old-fashioned way of cutting with chisel and hammer.

Dr. Dana had seen the instrument mentioned. He thought there was a good deal more in the surgery than there was in the burr. In one of the prominent hospitals in New York, with this burr he had known it to take over an hour to get through the bone. With the best instrument the surgeon must be trained in its use.

Dr. Sachs thought the question of time scarcely entered into the technique. He did not consider the fatal issue in so many cases the result of the modern operation.

Dr. J. W. Putnam of Buffalo was opposed to the statement that slowness makes no difference. He did not believe it possible to settle on one form of operation, because different surgeons will find that their own speed differs with the instrument.

(To be continued.)

---

**Massachusetts Vaccination Law before the Supreme Court of the United States.**—The case of Heming Jacobson of Cambridge, Mass., vs. The Commonwealth of Massachusetts was docketed in the United States Supreme Court on June 29. The point involved is the constitutionality of the Massachusetts law making vaccination compulsory. The law was upheld by the State courts.

# New Instruments.

## A NEW MODEL OF THE CLINOSCOPE.

By GEORGE T. STEVENS, M.D. Ph.D.,
NEW YORK.

For the purpose of making certain investigations and experiments in physiological optics, I found it necessary to modify my earlier model of the clinoscope, with the result that the newer model serves not only for physiological experiments, which can not be made by the earlier form, but it proves in several respects an advance on that form.

By reason of some changes in the mechanism the instrument can be made at materially less expense, it is more portable, being less than half the weight of its predecessor and the objectives are better seen.

As a result of the modifications in the design the

tubes are shorter and smaller. This permits of a convergence of about 15° for each tube for physiological experiments. When in ordinary practical use the tubes are restored to parallelism.

The reduction in the size of the tube does not reduce the apparent size of the objectives, since, owing to the diminished length of the tube, the image is apparently larger than in the larger tube of the earlier model.

The objectives are attached to the tubes in such a way that they may, with any dip of the tubes, remain in the vertical plane, an essential in examining the normal rotations of the eyes in convergence with depression of the plane of regard.

The posterior halves of the tubes do not rotate, and thus do not cause any variation in the level of the two sight holes. These last also, by being made very small, render the use of refracting glasses in general unnecessary. The anterior halves of the tubes are rotated on their axes by levers which replace the screw-gear, and thus substituting frictional in the place of the screw-adjustment.

After using the new model for three months in connection with and in constant comparison with the original instrument, I find it in all respects the equal of the earlier form and in some respects superior to it, besides being adapted to purposes of research beyond those to which the other was fitted.

In general, the principles of the original instrument are retained. The accompanying cuts represent the modified instrument, which has been skilfully made for me by Mr. E. B. Meyrowitz.

22 East Forty-sixth Street.

## THE MOUNT BLEYER ULTRAVIOLET CROOKES' TUBE FOR GENERATING THE VIOLET LIGHT.

By J. MOUNT BLEYER, M.D., F.R.A.M.S. L.L.D.
NEW YORK.

This communication is the forerunner of a series of experiments now under way to determine the exact clinical value of the ultraviolet light as produced from a Crookes' tube. Up to the present moment it is only my intention to register my discovery. I will say beforehand that already I am well satisfied with the results that I have thus far achieved and which I shall print later on. However, all those who have more or less tested the value of ultraviolet rays know their value in therapeutics.

I wish to bring this new method of generating these ultraviolet rays to the notice of the profession. I do so with the assurance that I am the first to make known the fact that these rays as I produce them in vacuum tubes have all the advantages over, and none of the disadvantages as compared with the Finsen electric-arc light, with all its costly and complicated accompaniments.

There are other new improved lamps for generating these ultraviolet rays, but I believe that there is no lamp which will give more quality and quantity of ultraviolet light than this Crookes' tube. I introduce this vacuum tube with the greatest of faith and hope it will prove itself as I represent it.

During my experimental research I put this tube through every sort of physical test known to us, and must say that the reaction tests found were very satisfactory to me.

The ultraviolet vacuum tube has many good qualities; it is a cold light and can be worked on either a coil or a static machine; it runs noiselessly, and no burns or marks are left on the patient after lengthy exposure; it will be found to be operated in the most simple fashion, and anyone having the slightest experience in *x*-ray work, can at once generate these ultraviolet rays; as the method of application is the same.

The color of the light that this tube gives differs in color from the Röntgen light, it being dark purple instead of the green *x*-ray.

The construction of this tube and the exhaustion of its gases also differ; the tube has a long life and can be operated for a long time without any deterioration to its rays.

Any one having given any time to the study of the physics of the vacuum tube knows the laws that these ultraviolet rays obey. My only object in this communication is to introduce to my colleagues this new ultraviolet vacuum tube with which I have been experimenting and now turn over to them for further clinical experience in the various diseases in which the ultraviolet rays are applicable. It is more than useless to take up more space or go into a detailed discussion of the physical laws which surround this ultraviolet light, as it all can be found in numerous works on this subject.

Physicists have done all that patient technical labor can do to formulate the true laws that govern these vacuum tubes, as far as we know.

To describe this ultraviolet Crookes' tube: It is exactly the same shape as an ordinary round,

x-ray tube, differing only in the quantity of the gases exhausted and the placing of the poles. It can be connected with either coil or static machine in exactly the same manner.

460 Lexington Avenue.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 4, 1903:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 360 | 12 |
| Diphtheria and croup | 325 | 47 |
| Scarlet fever | 157 | 14 |
| Smallpox | .. | .. |
| Varicella | 58 | .. |
| Tuberculosis | 247 | 123 |
| Typhoid fever | 45 | 9 |
| Cerebrospinal meningitis | .. | .. |

**The Paris Academy of Sciences.**—There is only one German among the members of the Paris Académie des Sciences—Prof. Robert Koch, who was elected in the place of the late Rudolf Virchow. Of the other six foreign members Austria and America contribute one each—Suess and Newcomb—and England four—Kelvin, Lister, Stokes, Hooker.—*Evening Post.*

**Sickness at Naval Stations.**—The sickness reported at the naval stations due to the overcrowding of the enlisted force on account of insufficient accommodations of the receiving ships, was predicted by Surgeon-General Rixey several months ago. While Congress was in session he recommended to the Secretary of the Navy that the receiving ship system be abolished, and that land barracks be erected at various naval stations for the preliminary training of recruits, and he expressed the opinion that epidemics were brought about by the crowding and other conditions existing on board of the receiving ships. Congress, however, failed to make the appropriation asked for, but better things are expected from the new Congress. —*New York Tribune.*

**The Strange Effect of a Bullet.**—A few days ago—according to the *London Mail*—M. Lecuier of Sugny, in the Ardennes, an old pensioner, who was wounded on the field of battle during the Franco-German war, and suffered from a tumor caused by a shot in the leg, underwent an operation. The bullet had been extracted in 1870, but the tumor continued, and, finally, Lecuier could not walk. The surgeons were greatly surprised in the course of the operation to find imbedded in the wound a coin of 10 centimes (a penny) bearing the effigy of Napoleon III, and the date 1856. The penny is believed to have been carried into the thigh by a German bullet, which had first struck the soldier's purse. The coin was bent in two and covered with powder on one side. It will be placed in the local museum.

**Brain Weights.**—Dr. Matiegka, in his extensive studies recently published on the weights of human brains, gives the following data, among many others: From 235 brains belonging to persons whose occupations during life were known, he makes a table of brain weights, arranged according to occupation, dividing the cases into six groups:

| | Class. | No. | Av. Wt. (Grams.) |
|---|---|---|---|
| I. | Day laborers | 14 | 1,410 |
| II. | Workmen | 34 | 1,433.5 |
| III. | Porters, watchmen, etc. | 14 | 1,435.7 |
| IV. | Mechanics, tradesworkers, etc | 123 | 1,449.6 |
| V. | Business men, teachers, clerks, photographers, professional musicians, etc. | 28 | 1,468.5 |
| VI. | Scholars, physicians, college men, etc | 22 | 1,500 |

Coachmen and truck drivers (14), showed 1,445.7 grams locksmiths, blacksmiths, and metal workers (21), showed 1,476.7; brewers, tavern-keepers, waiters, and others employed in making and selling liquors (16), showed 1,416.9—a low figure.—*The Sun.*

**A Russian Peerage Held by an Englishman.**—One of the most curious peerages and the only Russian one held by a British commoner is the Barony of Dimsdale of Essenden Place, Hatfield. The great-great-grandfather of the present holder of the title, Dr. Thomas Dimsdale, was specially retained to vaccinate Catherine of Russia, and performed the operation so much to her satisfaction that she gave him £12,000 ($60,000), and an annuity of £500 ($2,500), while she made him a councillor of State, and created him, in 1712, Baron Dimsdale with the prefix of Honorable. The late Lord Mayor of London belonged to this family.

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U S. Marine Hospital Service, during the week ended July 4, 1903.

### THE STRUGGLE OF SCIENCE WITH OLD AGE.

BY J. BANDALINE, M.D.,
PARIS, FRANCE.

For if any such thing may be found out, Medicine shall not be honour'd only for Necessity, but for a Guift, the greatest of earthly Donations that could be conferr'd on Mortality, whereof men, next under God, may be the Dispensers and Administrators.—BACON.

I.—IN one of Victor Hugo's charming poems, the "Légendes des Siècles," Hercules takes Satire, despised and derided by everybody, by the ear and brings her before Jupiter. Satire, prickly, black, disgusting, but calm, appears before the bar of Olympus evoking loud laughter from all the gods. Mercury presents her with a flute, and all urge her to sing. She sings of the sufferings of mankind. Phœbus gives her the lyre, Satire takes it and at once becomes great like humanity; she addresses herself to the frightened gods and cries: "*Place à tout! Je suis Pan. Jupiter, à genoux* "

Does not modern science remind you of Satire in the "Légendes des Siècles?" Miserable, despised by everybody, dressed in rags, "*ancilla generis humani*," it suddenly rose, took the lyre and began to sing its song of human suffering and of a brighter future. Like Satire, Science at once became greater and exclaimed: "*Place à tout! Je suis Pan. Jupiter à genoux!*" And modern humanity, upsetting all its idols, turned its eyes toward science, expecting it to vanquish suffering, old age, death. What a charming illusion, what a sweet dream to think of the freshness and the joys of the first twenty years of our life being added to the experience and the wisdom of mature age!

We all, however, know the inevitable approach of old age, and are ready, like Faust, to give our soul to the devil, if he will free us from the burden of our years, and but few people obediently subordinate themselves to this inexorable law. Cicero in his first book of the "Tusculana" relates that old Silen, the prisoner of King Midas, used to say that the first and greatest blessing for him would have been, not to have been born at all, and the second would be to depart from life as soon as possible.

An ancient sage, La Mothe de Vayer, says in his letters, that he would never have consented to come into the world if he had known before hand to what Providence had predestined him.

But however burdensome and tedious life may be, in spite of all the suffering and adversity it may bring, man and every living being in general clings to it and loves it. To live! To live! this cry comes from every heart.

And just as the love of living is the most profound and insuperable instinct of man, from times immemorial the desire to keep and prolong it has been paramount in scientific investigations: the short time of youth, this period of beauty and development of force, the age of highest earthly happiness, they have tried to prolong indefinitely.

Where are the wise men that, like Lavoisier and Chénier, would not express their regrets at being compelled to die without being able to communicate to the world the thoughts agitating their minds, or to leave it the discoveries that they foresaw? What a loss to science, thought, and art has been the premature death of such men as Archimedes, Mozart, Raphael, Descartes, Pascal!

To prolong human life would tend toward the development of science, the increase of our glory, and the ultimate perfection of humanity. At the dawn of civilization man tried all means within his youthful imagination to discover the elixir of youth. David thought that a young girl, sleeping with him in his royal bed, would be able to render him youth. Galen and Paul of Ægina believed in putting a healthy man on the stomach of old men, as the surest way to rejuvenate them. Arabian medicine considered the bezoares (a hard round substance found in the stomach of ruminants) the best antidote against infectious disease. The Chaldeans looked to the stars and different magical manipulations as a means of prolonging life. According to Suetonius, alchemy made its appearance in the second century B. C. owing to the efforts of Caligula. Related, as it was, to cabalistic teachings, it at once aroused great enthusiasm and many became adepts. Shrouded in mystery, having recourse to hieroglyphs, and being propagated by secret societies, alchemy counted among its adherents many eminent persons. During the long period of the Middle Ages we meet such names as Roger Bacon, Pica de la Mirandola, Raymond Lulle, Kircher, Van Helmont, Cardinal Richelieu, and the celebrated Arabians Avicenna, Avenzoar, and Averroes.

The alchemists of the Middle Ages zealously tried to discover the philosophical stone that was supposed to change all metals into gold. Since the thirteenth century, however, this stone was also supposed to be able to cure illness and prolong human life. Ever since that time the alchemists may be divided into two schools: the one represented by Raymond Lulle and Nicolas Flamel, forever seeking means of changing base metals into gold; the other trying to find out a special life potion, a remedy for all sorts of ills, attempting to cure by science all evils that man is heir to.

For thousands of centuries, they said, the sun had been pouring out his vivifying rays without being exhausted. Does not gold also, in a similar manner, retain its inalterable clearness? The earth, dying with each winter, arises to new life every spring, finding within itself a new source of fecundity. Is not nature, with its mystical power of retaining its own products, able to preserve youth and to increase life in sweet and undisturbed longevity?

These alchemists were the forerunners of future exponents of our new biology. They wanted to wrest the principle of life from Nature herself, imagining to revive old people by means of gold and to communicate to them a new soul and temperament. The ancients knew of the exciting action gold exerted on all the functions of the organism and made good use of it by combining it with phosphoric

acid. They were acquainted with the action of gold on scrofula, an illness described by Phracastor. In the eighth century the alchemist Geber compounded a red elixir from gold for the purpose of rejuvenating old people. During the Renaissance gold still held its place, being given even to children.

Under the name of "alcahest," Paracelsus brought out a liquid, a product of second distillation of a preparation of quicksilver, the immortal water (ignis aqua), gold of the horizon (ens primum), reduced, according to its inventor, to its finest molecules without decomposing it, and representing a universal remedy against all illness and even against death.

But these men, although the inventors of such potent remedies, did not possess the art of prolonging even their own life. Paracelsus died at forty-seven, Geber at fifty years of age.

To escape death there must be some change from the very first moment of birth. As the American biologist, Minot, says, old age is a phenomenon, beginning to make its appearance from childhood. Modern cytology teaches us that the cell nucleus consists of a series of granules—caryomicrosomes—made up of a peculiar mucous substance, rich in phosphorus (nuclein). These nuclein granules that readily take up various anilin dyes are united among each other by linine, which does not stain with these colors. The nucleus atrophies from our youngest age to old age. It constantly diminishes in volume, whereas the protoplasm becomes more abundant. In the perpetual consumption of the nucleus is revealed the reason of our getting old and dying. "From our youngest years we are dying day by day," remarks Bichat.

Humanity has always felt instinctively that great secret of life contained in the cell-nucleus. The people of legendary times devoured newly-born children as though they knew that the embryonal principle of the living world contained in itself the substances necessary for rejuvenation.

Modern science and biology have again returned to the cell and its nucleus. Schiller aptly remarks, in his philosophical letters: "*Wir gelangen nur selten anders als durch Extreme zur Wahrheit, wir müssen den Irrtum zwar erschöpfen, ehe wir zu dem schönen Ziele der ruhigen Weisheit gelangen.*"

During one of his last lectures at the Hôpital Necker, Huchard, that eminent clinician, exclaimed: "*On revient toujours aux premiers remèdes*" and highly recommended the use of yolk of egg as a subcutaneous injection. Owing to its ingredient of phosphorus, good results have already been obtained by this treatment in all conditions associated with subnutrition, like anæmia, phthisis, rhachitis, and diabetes of pancreatic origin. Instead of the yolk Lancereaux uses subcutaneous injections of lecithin (from 0.1 to 0.2 centigr.). This substance is found in the blood, the yolk, the sperma, and in general in all tissues possessed of great vital energy.

Desgrez and Zaky[1] prepared lecithin from hen's eggs by the classical method. Their lecithin is a combination of olein, stearic acid with glycophosphoric acid and with choline containing 8.62 per cent. of phosphoric acid and identical in its results with those obtained with lecithin by Danilewsky. Dogs that received lecithin by injection or per os very quickly increased in weight (in twenty-seven days a dog doubled his weight from 2,100 to 2,400 g.); the excretion of urea and nitrogen were increased, whereas phosphoric acid was decreased.

Clinical observations completely confirmed the experiments made in the laboratory. Patients that received lecithin noticed a marked improvement of the appetite with rapid increase in weight. According to observations of Bergnignan, from Huchard's clinic, an anæmic patient with an ulcer of the stomach gained about seven pounds in weight in fifteen days.[2] Without adhering to the cannibalistic customs of the ancient legends, medicine tries to obtain from nature a substance contained in the embryonal tissues of the organism, *i. e.* the cell and its nucleins, principles that possess the power of restoring new life. In its evolution, the fight against old age has passed many stages and was subject to many changes.

This problem, old as civilization itself—in fact, owing its origin to it—has been the cause of many dreadful errors, according to Schiller, until in our day it has worked its way "*zu der ruhigen Weisheit,*" turning to the cell as the origin of all mysteries of life and death.

II.—Our body is composed of an innumerable quantity of cells, each of them living its own life and keeping its own individuality. Each substance, says Goethe, is not a unit that is indivisible, but a collection of living beings, acting each by itself.

Life pulsates in every cell and is not confined to any one organ. All the physiological, pathological, and toxic phenomena are caused by cell changes, and there is no reason to suppose that death, disturbing the equilibrium and harmony between immensely small units, condemns them to non-existence. We know of marvelous experiments proving the vitality of various organs of an individual already dead.

Brown-Séquard cut off the head of a dog that had lived a long time in his laboratory and called him by his name. His eyes, though blinded with blood, immediately turned to the illustrious physiologist: the true animal knew his master's voice.

According to the principle of division of work, each cell has its own duties and does its part for the prosperity of the whole organism; the cell plays a rôle in heredity, it is the origin of new tissues, the motor of life acting on our organism.

The cells are our physiological "I"; they are born, develop, and die. The constant and unceasing decay of these cells constitutes the chief condition of our life.

Without the death of the cells of the salivary glands there can be no saliva, one of the chief factors in digestion, and, of course, of our life.

But with the death of each cell a part of our own being dies. Looked at in this way our organism constitutes a great cemetery, and our life processes a series of continual funerals. The division of work does not at all disturb the solidarity nor the unity of the cells. Just as in a well-organized State every citizen has his rights and duties, every cell fulfils its functions, sending out stimuli and receiving them, being at the same time connected with the nervous system, the slightest excitation of one cell immediately calling out a reaction in the whole organism. Living their own life the cells constitute the principal part of our "I," of our body; and whenever any of them die, a part of our "I" dies with them.

The cells of our organism live together, says Engelmann, but die separately. Nevertheless these partial deaths take place in our organism without any appreciable disturbance. Therefore death becomes the inevitable result of life. The individual is born only to die. The ovum, the muscles, the bones and the nerves are organs in which the life of these of other cells is expressed, and by developing and fostering these organs they become subject to a greater degree of disorganization and destruction.

The development of each being is nothing else but the constant invisible touch of death. Those actions that allow us most readily to distinguish the living organism from the dead are most intimately bound

to death. Thus anger, causing a sharp contraction of the muscles, the laugh that makes the face shine, the thought that wrinkles the forehead, the æsthetic joy that causes the heart to beat faster, are all accompanied by organic destruction—the death of cells. Without destruction there is no regeneration of life. Without death there is no life. Forever and everywhere life and death embrace one another.

Therefore, as though fulfilling the words of the Greek philosopher "*πόλεμος πατὴρ πάντων*," our life is a constant struggle with the various elements of which we consist, and on the result of this struggle depend the normal equilibrium of our organism, our health, our illness, life and death.

Schiller says:

"Mir gefallt ein lebendiges Leben,
Mir ein ewiges Schwanken und Schwingen und Schweben
Auf der steigenden, fallenden Welle des Gluckes.
Denn der Mensch verkummert in Frieden
Müssige Ruh ist das Grab des Muthes."

Another great German thinker, Kant, justly remarks: "*Dank sei der Natur für die Unvertragsamkeit, für die missgünstig wetteifernde Eitelkeit für die nicht zu befriedigende Begierde zum Haben oder auch zum Herrschen! Ohne sie würden alle trefflichen Naturanlagen in der Menschheit ewig unentwickelt schlummern. Der Mensch will Eintracht, aber die Natur weiss besser, was für seine Gattung gut ist; sie will Zwietracht.*"

Old age, according to what has been said, is nothing else but the triumph of one sort of element over the other.

But what kind of elements are they?

In the beginning of the nineteenth century the curtain of this mystery was raised a little by the naturalists. Flourens said that some organisms possess the individual and effective force of productivity. Tremblay investigated the regeneration of polyps, Bornet of the worms, Réaumur of the crawfishes, Cuvier of deer, Flourens of salamanders. All these authors had the vague idea that old age is actually the stopping of the production of certain cellular elments.

Later on, Roux of Breslau expressed the marvelous point of view that in man two great systems—the mesoderm and the ectoderm—are in a constant struggle. After him, Demange, Bastein, Chacot thought that senility of the brain consisted in atrophy of the parenchymatous and hypertrophy of the interstitial tissues. Golgi and Weigert have shown that the nerve cells become the prey of the neuroglia.

By brilliant and detailed experiments Metchnikoff showed that the view of Bastien and Charcot was the true solution of this problem and that old age is an atrophy *sui generis* appearing in the triumph of the mesoderm—common elements—over the ectoderm—noble elements.[3]

Noble elements being specific for every organ (liver, kidney, spleen, heart, and brain) are better differentiated than the common elements. Besides they are the foundations upon which the functions of life rest, they constantly elaborate and secrete poison, and on account of this they soon get exhausted and lose their vitality earlier.

There is nothing astonishing in the fact that finally they become the prey of the common elements, especially of the elements of the mesoderm that are more vigorous and numerous.

In adolescence and manhood the equilibrium is maintained between them, because the noble cells secrete an antitoxin that neutralizes the pernicious influence of the hostile elements. But in the long run this antitoxin diminishes in quantity and the greedy common elements of the mesoderm, the so-called mononuclear macrophagues begin their attack upon those elements, the polynuclear microphagues, and destroy and displace them, the conscious defenders of the noble elements of our organism. The latter therefore disappear, tired of the unequal struggle and deprived of the help of the microphages that succumbed to their enemies. The latter being coarser and stronger displace them and quickly develop in every direction. The epithelium disappears from the liver and the kidney and the nerve cells from the brain. Cirrhosis of the liver, kidneys, and heart develops and the functions of these organs become impaired. Finally the two great systems of the organism (the vascular and the nervous system) yield to the enemy and the common elements overrun the noble ones. Then arteriosclerosis, this "rust of life," sets in—it marks the turning point in man's life. But we will let Victor Hugo, the illustrious author of the "*Feuilles d'automne*," express his sentiments on this point:

"Effacer de son front des taches et des vides,
Vieillir enfin, vieillir! comme des fleurs fanées,
Voir blanchir nos cheveux et tomber nos années,
Rappeler notre enfance et nos beaux jours flétris,
Boire le reste amer de ces parfums aigris,
Etre sage et railler l'amant et le poète.
Et lorsque nous touchons à la tombe muette,
Suivre en les rappelant d'un œil mouillé de pleurs
Nos enfants qui déjà sont tournés vers les leurs.
Ainsi l'homme, o mon Dieu! marche toujours plus sombre
Du berceau qui rayonne au sépulcre plein d'ombre."

It is clear that an exact knowledge of the elements participating in the above struggle would probably enable us to paralyze the efforts of the common elements as far as biological laws will permit. The macrophagues being a source of danger to our organism and the only cause of old age, ought to be eliminated from our system. We must deprive them of their capacity for pernicious influence upon the greatest good—human life. An antiphagocytic serum, prepared in this sense, has produced its demolishing effect not only upon the macrophagues, but also upon their enemies, the useful microphagues.

If the enemy, *i. e.* the common cells, is able to overcome so easily the noble cells, it shows that the latter do not react against the enemy like in youth and manhood. When full of vigor and freshness, the noble elements successfully repel the enemy, thanks to the toxins which they secrete.

Instead of striking at the macrophagues directly, Metchnikoff conceived the idea if possible to fortify the noble cells, help them in their struggle, make them sufficiently resistant. It is the cells of the liver, kidney, and brain, etc., that are especially in need of this help. Thus Metchnikoff arrived at this method, the essence of which is founded on the nature of the cytotoxins—cellular poisons—a method that at present attracts the attention of the whole medical world.

III.—Since antiquity, blood has been used as a potent remedy in various hopeless ills. While the audience in the Colosseum listened to the salutation of the dying gladiators, "*Ave, Cæsar, morituri te salutant*," Roman women hastened to the arena to drink the blood of these victims in the hope of recovering from epilepsy.

It is said of Louis XI. that in order to escape old age he used to drink a child's blood, brought to him fresh daily. Transfusion of blood was the next logical step. The first mention of this procedure is in the work of the celebrated Libarius, who died in Coburg in 1610. The discovery of the circulation of the blood by Harvey in 1619 and communicated to the world in 1628 gave renewed impetus to the expectations and hope placed in blood transfusion.

The first authors spoke enthusiastically of the new method, destined to cure hopeless illness, to restore youth to the aged, and to prolong life indefinitely.

Wren in England and Masion in Germany promulgated this new doctrine. In England the first trials were made on animals. Later Emmerets and Denis in Paris took the risk of the operation in a man, other physicians, however, like Le Martinière and Perault, protesting against it. Lower, King, Riva, and Manfridi, however, followed the example of Denis, one physician even submitting himself to the procedure. On June 15, 1667, blood was for the first time transfused into the body of a young man of sixteen, who was in a state of great prostration owing to copious bloodletting. After operating on him by Denis's method the patient at once became conscious, his power, memory, and good humor returned to him.[4]

Soon after this a serious occurrence attracted the attention of all Paris. A maniac, Antoine Mauroy by name, who for seven years had been subject to attacks of insanity, after having been treated by various means without result, including eighteen venesections, consented to pass through the operation of blood transfusion. Denis and Emmerets made the transfusion on December 19, 1667, in the presence of a great number of physicians and others. The operator was unable to transfuse more than six ounces of calf's blood, as he was obliged to stop on account of great weakness of the patient. On December 21 the operation was repeated. After the infusion of a pound of calf's blood, the patient's hands became warm, his pulse stronger, and a profuse perspiration set in. After the removal of the cannula he fell into a sound sleep. Two days later he had profuse nose-bleed and the urine became black. A third transfusion was done at the end of January, but the patient died during the night. His wife began an action against Denis, the result of which was that the tribunal on April 17, 1668, prohibited, under pain of criminal responsibility, the operation of blood transfusion, as not being approved by the faculty of medicine. For more than 150 years this method was forgotten, when Blundell, Dieffenbach, and Magendie again revived it.

The work of Oré of Bordeaux shed some light on the theory of blood transfusion. The infusion of artificial serum, corresponding as it did to the same laws, but being less dangerous than blood transfusion, nearly entirely replaced the latter.

The discovery of the cytotoxins, these poisons of animal origin, belongs to a period when transfusion of blood was made from mammals to man. The fatal result that occasionally accompanied these transfusions and the very serious complications that frequently followed, as coagulation of the blood, the formation of thrombi and infarct in the lungs, occurred, according to Panum, Ponfick, Hayem, and Landois, because of the decomposing effect exerted by the blood of an animal of another species on the red and white blood cells of man. But as blood transfusion was no longer practically used, the discovery of the cytotoxins, made twenty-five years ago, was quite forgotten.[5]

Inquiries into the bactericidal properties of blood sera of various animals again revived the question concerning the cytotoxins. In 1889 Metchnikoff showed the analogy between the bactericidal power of the sera and their property of decomposing the red blood-cells.

The labors of Daremberg and Buchner definitely determined that the destruction of the bacteria and the red blood cells by sera is subject to the same law, and proceeds according to the same mechanism. The discovery of artificial cytotoxins was made much later.

Belfanti and Carbone for the first time in July, 1898, noticed the existence of a toxin, developed in the serum of animals, cured by the blood of animals of another species. Thus the serum of a horse into whose peritoneum a quantity of rabbit's blood had been injected, became virulent to the rabbit. The serum of a dog that had been treated with the blood of a rabbit, was a still more potent poison for the latter. Belfanti and Carbone found that these sera are very poisonous for animals giving us blood for injection, and not at all so for animals giving serum only.

Bordet working under the guidance of Metchnikoff was brought to the same result as the Italian investigators. Bordet proved a complete analogy between the bactericidal force and the hæmolytic nature of artificially prepared sera. In both cases it is the question of specific poisons, consisting of two substances, the first of which, alexin, is preformed in a normal animal, the other one, the so-called "substance sensibilisatrice," is formed by injection of the blood of one animal into an animal of another species or by bacterial products.

"Thus," says Metchnikoff, "the theory that there are two substances united for the formation of a poison for both the erythrocytes and the bacilli cannot be doubted."

The German savants, Ehrlich and Morgenroth, in their remarkable articles on hæmolysins, confirmed this theory. According to them Metchnikoff's "substance sensibilisatrice," called by them "Zwischenkörper" or "intermediate substance," exerts an energetic action on the hæmolytic ferment—the alexin: the Zwischenkörper themselves are not able to decompose the red cells, but attached to the alexins they attain great hæmolytic power. These fundamental facts concerning hæmolysins led Metchnikoff[7] to suppose that it would be possible to prepare artificial cytotoxins that would be specific for all sorts of elements, and by their means to regulate the functions of the abnormal cells.

If you inject the spermatozoa of a bull into the peritoneum of a porpoise, the spermatozoa will be eagerly attacked by the small white round cells—the microphagues and the macrophagues. As a result the peritoneal fluid and the serum of the porpoise become a poison for the bull's spermatozoa, stopping their movements. Thus Landsteiner obtained the spermatoxin. If you inject into the peritoneum of a porpoise the emulsion of a rabbit's kidneys, it suffices to inject a little of the resulting serum into a rabbit, in order to provoke a severe albuminuria and death by uræmia. On autopsy, necrosis and great changes in the tubuli contorti are found. This is the nephrolytic serum obtained by Lindemann. If a duck is injected with emulsion of dog's liver, a serum very virulent for the liver cells of the dog is obtained; the injection of this serum into a dog rapidly causes the death of the animal, with all the signs of hepatic insufficiency (diminution of uric acid and increase of ammonium salts). The post-mortem findings resemble those of acute yellow atrophy, or of phosphorus poisoning. We have to deal in this case with a hepatolytic serum.[8]

If the emulsion of a rat's spleen is injected under the skin of the porpoise, a serum will be obtained, according to Metchnikoff, that will decompose the leucocytes of the rat.

All these cytotoxins are specific; they decompose those elements from which they originate. Thus the nephrolytic serum attacks the kidneys, leaving

all other organs intact; the hepatolytic serum attacks only the liver.

The discovery of artificial cytotoxins awoke the idea in Metchnikoff, whether it would not be possible to profit by them through the regulation of certain cellular functions during illness and old age.

Are small doses of cytotoxin able to exert an exciting influence upon the corresponding elements? It has long been known that small quantities of certain poisons have a stimulating effect on organs that are paralyzed by higher doses. In the third volume of Duclaux's treatise "Micrologie," a series of examples is given in which fermentation proceeds more quickly owing to the presence of small doses of poisons like alkaloids and antiseptic substances. Schultz has shown that many substances poisonous to yeast, like mercury, iodine, arsenic, if added in small quantities, hasten fermentation. Effront made use of this fact to increase the production of alcohol. He subjects yeast to the action of hydrofluoric acid, and thus enhances the fermenting power of the yeast.[9] Laboratory experiments with small doses of cytotoxins were attended with the following results: The injection of small doses of hæmolytic serum, prepared by the injection of rabbit's blood into the peritoneal cavity of a porpoise, increases the quantity of hæmoglobin in a rabbit. The injection of small doses of leucolytic serum, prepared by introducing into the peritoneum of a porpoise an emulsion of mesenteric glands of the rabbit, causes in the rabbit a perceptible hyperleucocytosis. All these facts combined induced Metchnikoff to use the hæmolytic sera on man, especially for the cure of leprosy.[10]

Carrasquilla, in 1891, treated lepers with horse serum, obtained through the blood of a leper, with a resulting general amelioration of their condition.

Laverde obtained the same results from the serum of a goat, which he had injected with the expressed and filtered juice from human leprosy tubercles. Assuming that the good results obtained by Carrasquilla and Laverde were not dependent upon the products from Hansen's bacillus, but upon the cytotoxins elaborated in the system on account of the injection of human blood or human tissue, Metchnikoff injected lepers with a hæmolytic serum, obtained by treating a goat with defibrinated blood. This treatment incited stronger hæmatopoiesis, and caused an increase of hæmoglobin.

Relative to this, Dieulafoy says: "*Il n'est même pas téméraire d'affirmer que l'application de faibles doses de cytotoxines peut bouleverser de fond en comble la thérapeutique.*"

New horizons open for medicine through these sera, direct reconstructors of the noble cells. Long prior to most of these discoveries, in 1889, Hayem exclaimed prophetically: "*L'avenir est à l'hématologie. C'est elle qui nous apportera la solution de grands problèmes nosologiques.*"

It is more than twenty years since Hayem published his remarkable work, "*Du sang et de ses altérations anatomiques*," in which, on the strength of clinical experience and exact observation, he lays down the following law: Every chronic anæmia is accompanied by a corresponding diminution in the quantity of blood. There is no doubt that the different forms of anæmia, like chlorosis, pernicious anæmia, bothriocephalus and anchylostomium, anæmia, hidden tumors of internal organs, cachexia, are really different kinds of lowered hæmatopoietic power, dependent upon the variety of poison and the organ affected.

We regret to say, that we do not as yet know hæmocytic formulas corresponding to various diseases like the leucocytic formulas proposed lately by Vidal and Ravaut, for the distinction of different pleuritic fluids.[11]

These authors show the possibility of discerning whether, in a given case, we have to deal with a serofibrinous inflammation of the pleura, due to the tubercle bacillus or the pneumococcus, or with a hemorrhagic infarction, or with an exudate developing in persons afflicted with heart trouble or disease of the kidneys, or cancer.

In the first case we find in the pleuritic fluid exclusively small lymphocytes and red blood cells; in the second case, a great number of polynuclear and a certain quantity of mononuclear cells, that, like real macrophagues, contain in their protoplasm polynuclear cells. It is clear that in the fluid of a pneumococcus pleuritis the process of attack and defense should be well marked. In the third case we find degenerated polynuclear lymphocytes, with dividing nuclei and changed neutrophilic granulation.

In his lectures on January 15, 22, and 29 of this year, Dieulafoy, discussing this question, showed a series of cases in his clinic at the Hotel Dieu where these cytodiagnostic points were of the greatest value. It would hardly be necessary to speak of the value of employing this measure in forms of pleurisy of obscure origin in young people, when, if the tuberculous nature should be disclosed, proper individual hygiene will save the young life.

With blood diagnosis it looks somewhat different. During disease the blood may be changed as to its physical, chemical, or histological qualities. The changes of physical and chemical constitution are not as yet well known. Concerning the histological changes, the credit belongs to Hayem, of having paved the way to a diagnosis of doubtful cases. Increase of the polynuclear elements, diminution of the hæmocytes and loss of hæmoglobin constitute the principal changes.

Two months ago, Milian[12] addressed a communication to the Medical Society of Paris, regarding the differential blood diagnosis between epithelioma and sarcoma. The author found that in round-celled sarcoma there is no leucocytosis nor anæmia; on the contrary, the number of erythrocytes rises to six or seven million per c.mm. According to Tuffier, persons suffering from sarcoma, but not yet cachectic, are never pale.

Picchi and Pieraccini, in their investigations on typhoid-fever patients, try to give a hæmocytic formula for that disease.[13] Tuffier places great confidence in their article, and concludes his "notes hématologiques" with the following significant words: "*L'hémodiagnostic et le cytodiagnostic sont des méthodes qui doivent aujourd'hui remplacer la laparotomie exploratrice, ou tout au moins en réduire considérablement les indications.*" It remains for the chemist and the bacteriologist to decide the question of the relation between different pathological processes and changes of the hæmocytes regarding their form, number, physical and chemical qualities, and, on the base of this relation, to connect different chemical pictures with certain forms of changed hæmopoiesis.

Probably it would be possible to enhance the hæmatopoietic powers in different pathological processes by means of specific hæmolytic sera, as was shown for leprosy by Metchnikoff and Besredna.

IV.—Stimulated by Metchnikoff's work on old age as an atrophy *sui generis*, Marinesco made a series of interesting observations on the nerve cell which plays such an extremely important rôle in all vital processes.

Normally, nerve cells of the gray matter and of

the ganglia, so-called somatochromes, contain in their protoplasm elements that stain deeply with the basic aniline dyes. These elements, that Nissl called chromophiles,[4] look sometimes like irregular little blocks dispersed without order in the cell body, and sometimes like rods, or merely like a series of simple granulations. They are principally disposed around the nucleus extending into the protoplasma branches up to the first bifurcation. They are not found in the branches of the axis cylinder. They are not present in the embryonal nerve cell, and appear only when the cell begins to perform its proper function. Marinesco called them kinetoplasma, on account of their dependence on physiological cell activity. These elements represent the storehouse upon which the nerve cell may draw when in need, their quantity changing according to the repose or activity of the nerve cell.

In old people, especially those that have died of old age, Nissl's chromophiles are diminished in size and quantity, looking sometimes like granulations. This last change Marinesco calls chromatolysm of old age, taking place at or near the nucleus and involving the entire mass.[5] Besides this, there is in the cytoplasm a greater or smaller quantity of pigment representing the product of disorganization of evolution of the cell itself. As the individual gets older the pigment increases, and, coincidentally, the respiratory and nutritive functions of the nerve cells diminish; their prolongations decrease in number and their ramifications disappear. Gradually total cell atrophy sets in, and thus pigment transformation is complete.

In all his specimens Marinesco never saw macrophagues demolishing the nerve cells. Still, in 1896, he found that nerve cells injured in their vitality became the prey of the neuroglia cells, and he therefore called them neuronophagues. In some pathological cases these neuroglia cells start the whole destructive process. Thus Nissl never found leucocytes in the perilymphatic spaces of paralytics while meningitis or encephalitis was present; neither did he meet with any in the cytoplasm of nerve cells. The nuclei found in groups near these cells are undoubtedly those of neuroglia, according to the investigations of Ramon y Cajal and Lugard.

It is evident that in the nerve cell, just as everywhere else, a struggle takes place during our entire lifetime. For all vital processes and the proper performance of all essential functions of the nerve cells, the equilibrium of the nerve cells and the neuroglia is necessary.

Marinesco observed the remarkable fact that the tissue and cells of neuroglia of old people are more developed than those of a young man, proving the existence of an antagonism between these two different cells.

The nerve cells and neuroglia cells of an embryo develop progressively in number and size.

Marinesco found that the neuroglia cells of newly born children were larger than those of adults; as the children grew older, these cells gradually diminished in size, dwindling down to a small nucleus surrounded by a small amount of protoplasm.

The neuron elaborates the toxin that checks the development of the neuroglia cell and preserves the nutritive equilibrium in the central nervous system. Whenever the chromophiles of the nerve cells have lost some of their vitality the neighboring neuroglia cells increase and attack the nerve cells. This has been experimentally produced, by Ballet and Duthil, by pressure on the aorta (*vide* article by Soury) and also by cell death.

Marinesco tries to explain the atrophy of the cell not only by its struggle with the neuroglia, but also on the ground of insufficient chemical synthesis of the nerve cells.[6]

The normal life of the nerve cells takes place owing to the equilibrium between the processes of chemical synthesis and functional destruction of the effete elements.

If this equilibrium is disturbed, if after the process of chemical decomposition phenomena of chemical synthesis do not occur to replace sufficiently the loss of substance, morphologic disorganization of the nerve cell begins. The cell decreases in size and a diminution in the number of chromophiles takes place, chromolysis and pigment transformation of old age set in.

As a practical result of his investigations Marinesco thinks that it is necessary to keep up chemical synthesis of the nerve cells. For this purpose he offers a dynamogenic substance like the serum of young animals or the juice of very young organs: "*Ainsi' du reste, que l'a proposé Metchnikoff, le suc emprunté à des organes tres jeunes et le sérum des animaux jeunes pourraient stimuler l'énergie affaiblie des éléments nobles et retarder dans une certaine mesure les phénomènes de la sénescence*," —says the author at the end of this report to the Academy of Sciences.

Thus we see that modern biology has one clear and well-defined aim in its struggle with old age: to restore the equilibrium between the noble and the common elements. "Restore this equilibrium," says Metchnikoff, "and you will take away the dread of death. The necessity of dying will then become more endurable and the expectation of a natural death, which is nearly always absent at present, will then develop freely."[7]

Life undoubtedly would become easier and less austere, if this instinct were well developed. Justifying the proverb of Confucius, "A long life is a long chain of suffering," mankind, arrived at a certain age, lives constantly in fear of death, this by itself injuring the nervous system.

"Pallida mors aequo pulsat pede
Pauperum tabernas, regumque turres."

The necessity of dying is constantly before the mind and worries it at all times. It would be better to follow the example of Themistocles, who answered a sophist proposing to teach him mnemonics, that it would be better to learn the art of forgetting.

The coming generation must develop in itself the instinct of natural death and indifference toward it. Metchnikoff has indicated the way that will bring people earlier or later to this ideal.

Nearly three centuries ago, Descartes, the celebrated author of the "Méditations," wrote: "*Au lieu de trouver un moyen de conserver la vie, j'ai trouvé un autre bien plus sûr; c'est celui de ne pas craindre la mort.*" Metchnikoff arrived at the same conclusion, but the microscope enabled him not only to confirm the philosophy of Descartes, but also to indicate the ways and means of realizing it.

V.—Modern science plays a great rôle; its consoling results and its ingenious applications in practical life will become to humanity as much a necessity as the oxygen that we inhale and the bread that we eat. Man is made up of a biological federation of cells constituting his personality.

Food must be introduced into the stomach to enable the heart to beat for everything human, noble, and grand; food is necessary in order to allow the brain to comprehend and accept everything that human genius discovers, to enjoy the charm of science and art, because human life should not give rise to weeping and sorrowing. Life, the bond that unites the naturalist and the Philosopher,

must look to science for its further development, its prolongation, and its gradual perfection.

To the modern biologist, the partisan of experimental science, the study of life ought to be a source of joy and delight for body and soul.

Life ought not to condemn a man to eternal suffering and a burdensome old age. The progress of hygiene and serum therapy, that has already revolutionized medicine, gives us the privilege to think that, although not desiring the long life of Methusalem, we still have no reason to agree with Tacitus when he says: "*Vita humana non est longi-evi spatium.*"

When plenty of fresh air disperses the foul odors of large towns; when electricity will make life easier by quieting its suffering; when universal peace will eliminate death on the battle-field; when humanity will lay aside its wild martial instincts, inherited from Roman civilization; when it will find its ideal not in the weakening principle of hate, but in the vivifying force of common love—then the longed-for reign of longevity will come, governed by natural laws. Two thousand years ago Aristotle, the father of philosophy, the greatest biologist and perhaps the first among the sociologists, said: "Whoever travels much can convince himself how everywhere men love one another and sympathize with one another." It has been shown that the length of human life constantly increases, and who knows but what the prospect of a centenarian existence, that now falls only to a chosen few, may not in the twenty-fifth century become a general law?

But how many centuries of work and indefatigable labor remain to men before they will view the promised land? Nearly thirty centuries have passed since under the sky of Lebanon's cedars the second chapter of Isaiah was first pronounced. But neither our children nor our grandchildren will see this happy time—the triumph of science, the highest incarnation of truth. That recalls a little story. In a small Italian village a doctor explained to the peasants the possibilty of curing completely many contagious diseases and the future triumph of science over death. An old man with white hair approached the lecturer and squeezed his hand passionately. "I will not see it, it is true," he said, "but I will die more tranquilly since I am persuaded that the coming generation will suffer less."

We hold ourselves responsible before our descendants, and that is the reason why we are obliged to develop our brain for the amelioration of the destiny of posterity, whom we will not see, but to whom we are responsible.

But will this really require centuries? The world's evolution follows the law of progressive and hastened movement.

It required millions of years to change the foggy spots into harmonious solar systems. It required hundreds of thousands of years before our earthly rind passed through different geological epochs. It took hundreds of years before we passed from one historical epoch to another.

And in history we see what follows: What required hundreds of years in humanity's childhood is realized nowadays during a century, sometimes during a half century, at times during ten years, because the inventions of human genius have worked wonders in the struggle with nature.

Modern man in ten years can do more than his ancestors could in a century. That is the mechanical law of progressive and hastened movement that burns in our soul like a powerful fire.

With foolish rapidity we are flying on the feathers of Pegasus; we dream of skies higher than ours, of a Far West not known to geographers or astronomers.

We have in mind that Excelsior where all noble ideals will meet, as well as all those whose souls, according to Shakespeare, are full of "the milk of human kindness."

Not only will the various periods of our life become longer, but old age itself will become more quiet, more worthy of human personality, and the approach of death will hardly be perceived. It will come like sleep to the tired workman.

Science gradually reveals to us the intimate relation that binds the whole creation to its Creator, and humanity will understand the law of community of interest in the relations of all the elements of the world. Light-heartedly man will reconcile himself with death coming to him like a quiet sleep, making an end to his conscious life. Returning to earth, we return to the first source of our life According to the poet:—

"Souvent dans l'être obscure habite un dieu caché
Et, comme un œil naissant couvert par ses paupières,
Un pur esprit s'accroit sous l'écorce des pierres."

And then the great words of the Bible will be clear to us: "And they did tell each other of the clemency of the Creator, passing from grave to grave."

# THE CLINICAL IMPORTANCE OF ALBUMINURIA.*

By HENRY H. SCHROEDER, M.D.
NEW YORK.

NOTWITHSTANDING the frequency with which the subject has been discussed, there seems to be a marked difference of opinion in regard to the value of albuminuria as a sign of present or future changes in the kidneys. A decided degree of indifference is evident to the writer as well as to others whose work brings them into correspondence with physicians throughout the country, the communications received showing that albuminuria is often considered to be trivial and unworthy of attention. This brief contribution is based upon thirteen years of experience in life-insurance work, and is given with the hope that the importance of albuminuria may be emphasized by the presentation of the subject from a somewhat different standpoint than that from which it is usually considered. It is probably well known that in insurance companies all information is carefully and systematically filed, each individual record being added to, perhaps for years, and it often happens that some very interesting histories are brought to light when the death claims come in. It is from such material that the writer has endeavored to glean a few facts in regard to topic under discussion. It frequently happens that some heretofore unsuspected condition is discovered in its early stages by the life-insurance examiner, which may have made such progress as to become a serious matter before the notice of the patient or his medical adviser is directed to it. Perhaps no class of cases is more benefited in this way than those mentioned by Osler in a recent article. He refers to the business men who, as a rule, work under pressure early and late, leading a strenuous life, combined, probably, with three hearty meals a day, two or three glasses of spirits, and anywhere from five to ten cigars. After fifteen or twenty years of such life, the "waste-pipes," as Osler calls the kidneys, are often the first to show signs of ill-usage. Such a man receives a rude shock when his application for insurance is rejected and he is informed by his physician, to whom he has been referred, that his urine contains a trace of albumin and a few hyaline casts. Osler cites several cases in which such patients, having accidentally learned about their physical conditions, began to lead a new and rational life at the age of fifty years, and were still living after a lapse of ten to fifteen years, though a trace of albumin and an occasional tube cast were still present in the urine.

That we have been steadily gaining in knowledge as to the prevalence of Bright's disease is suggested by the tables of Dr. E. J. Marsh, who has compiled the mortuary statistics of one of our large companies. In the first 1,000 deaths of the company, beginning in 1843, it was not once given as a cause of death. In the second 1,000 only 11 deaths were recorded, while now, even among those under forty-five years of age, there is a proportion of 3.5 per cent. of the total mortality in that period of life, and a proportion of 6.66 per cent. in all ages. These figures do not indicate that the disease is more frequent now than forty or fifty years ago, but that we have become better able to recognize the nature of the ailment. It is a well-recognized fact, also, that the above figures would be considerably augmented did they include the cases in which the patients dying of acute, or even chronic, diseases, had unsuspected nephritis which was either the chief or contributing cause of death; for instance, deaths from apoplexy, arteriosclerosis, and cardiac disease are often reported as such, though kidney disease happens to be the chief or causative factor. Dr. S. O. Vanderpoel, in discussing an article read recently by Dr. Edward Lambert, is reported to have said that though many applicants refused fifteen or twenty years ago on account of albumin are still alive, a careful collation of the statistics of such cases shows that from four to five times more of these rejected applicants are dead than ought to be, according to the normal expectation of life in men of their years; and, further, that albuminuric individuals seldom live out more than one-half their expectation of life. This statement is important, as it is based upon facts and not theory, Dr. Vanderpoel representing a company which has spared neither trouble nor expense in investigating its rejected risks for the purpose of classifying its substandard rates.

Preventive treatment is justly looked upon as one of the most important features of modern medicine; when, then, there are any danger signals to warn us of even a possibility of future trouble, it seems strange that any physician should neglect one which might be the precursor of such a grave disease as Bright's. Yet members of the medical boards of our insurance companies are in daily receipt of opinions from physicians in good standing that some individuals who have been rejected on account of albuminuria are quite healthy, having satisfied themselves to this effect after no more observation than the chemical examination of one of possibly two samples of urine. In many instances this is partly the fault of the patient who fails to be impressed with the importance of further observation of his case, or does not wish to incur much expense. The careful and painstaking physician will refuse to waste time in such instances, knowing that only extended observation of the disorder will be of any value. Dr. F. E. Sondern of this city has assured the writer that he has found signs of incipient kidney disease in from 60 to 70 per cent. of the patients who came to him after rejection on account of albuminuria. This would seem to be a large proportion, but even were it much less, there would still be enough to justify the most careful observation on our part. It is, of course, quite true that a great many of these cases will recover without medical advice or aid, especially when the exciting cause is a temporary one and the individual leads a temperate life without mental or physical stress, for there is every reason to believe that spontaneous cure may occur in albuminuria or even in incipient Bright's disease just as it may in incipient phthisis.

It is quite conceivable that the terms "functional" and "physiological" albuminuria have led to misconception as well as to indifference; the latter term at least should be avoided, as in the present state of our knowledge all albuminurias are pathological, being due to some disturbance or faulty process in some part of the human economy, even though the kidney tissues are still intact. According to the theories of Semmola and his school, functional albuminuria is caused by an excess of diffusible and unassimilable albumin in the blood (hetero-albuminæmia), this condition being due to some failure in metabolism. This unassimilable albumin is eliminated chiefly by the kidneys, and, unless checked, gradually produce irritation and parenchymatous and interstitial changes in their structure. The above-mentioned investigators found that blood from albuminuric patients contained an excessive

*Read before the Society of the Alumni of the City Hospital, April 8, 1903.

amount of diffusible albumins; that the injection of this blood into dogs caused albuminuria in direct proportion to the amount of diffusible albumin contained in the blood injected. Sir W. Roberts practically supports this theory in his statement that a solution of hæmoglobin in the serum precedes its appearance in the urine, and that the symptoms of kidney affection which are sometimes present are caused by the irritation of the hæmoglobin passing through these organs. These views would explain the fact that albuminuria can be greatly reduced or cured so long as it remains functional, and that it is influenced by diet, the amount of albumin excreted being proportional in a considerable degree to the amount ingested. On the other hand, if nothing is done, the attacks are liable to continue, becoming more and more serious as the patient advances in age and the metabolism becomes less and less active. Thus the metabolic albuminuria, which at first was paroxysmal and functional, will become organic, and structural changes will take place owing to the constant irritation, the condition then passing into one of fully developed Bright's disease. Strümpell believes that almost every pure albuminuria is a direct sign of an abnormal perviousness of the walls of the glomeruli due to pathological changes in the epithelium. These changes are induced by disturbances of nutrition in the epithelium of the glomeruli, such as arise from anomalies in the circulation (as arterial or venous stasis) from toxic or infectious influences which have reached the glomeruli, or from other circumstances. In these cases the changes in the glomeruli, says Strümpell, are not always of a severe or permanent nature, and consequently we often see a slight albuminuria appear under widely differing conditions and rapidly pass off again. Osler also believes that in all cases the presence of albuminuria indicates a change of some sort in the glomeruli, the nature, extent, and gravity of which it is difficult to estimate; so that other considerations, such as the presence of tube casts, increased arterial tension, the general condition of the patient, and the influence of digestion upon the albuminuria, must be constantly kept in mind.

This paper is too brief to allow of a thorough presentation of all the theories with their modifications which are held, but it was thought admissible to give a superficial view of the leading ones in order to show that, however much they differ in other ways, they agree at least in the fact that the structure of the kidneys is liable to permanent damage when albuminuria is allowed to go on without interference. It is admitted that albuminuria may sometimes come and go spontaneously, but it should not be called physiological for that reason any more than an acute coryza or indigestion should be considered physiological. The patient recovers from his albuminuria in such cases without aid, perhaps, more from good luck than from good management, the exciting causes having probably been dietetic errors, over-exertion, cold bathing, or excesses of any kind.

When albuminuria is associated with high arterial tension, thickened arterial walls or hypertrophy of the heart, and renal casts are found, we may be sure that organic changes have taken place. Usually, the first of these signs to appear is a high-tension pulse, and most writers are reluctant, if not absolutely unwilling, to believe that no structural changes exist when this sign is wanting. No less an authority than Osler writes that after the age of forty, the state of the arteries is far more important than the condition of the urine. While this holds true in perhaps the majority of cases, the writer, as well as others, interested in examining for life insurance, has met with many cases of well-marked albuminuria with granular casts, in which none of the above-mentioned train of concomitant symptoms has appeared at the time of examination, nor for years after, as will be shown in some of the cases to be cited later. This has occurred so frequently that the writer does not hesitate to assert that it would be as excusable to wait until cavities had developed before making a diagnosis of tuberculosis of the lungs, as to wait in all cases for a long train of symptoms in addition to albuminuria before making an effort to prevent chronic nephritis or to retard its progress, if already existent. Dr. Bradford, perhaps, accounts for this by his statement that the arterial changes in some forms of chronic nephritis are restricted to the vessels of the kidney itself. In these cases the kidneys are shrunken and fibrous, the capsule is thickened and leaves a granular surface on stripping, and there is comparatively little hypertrophy or arterial change to be noticed except in the renal vessels.

The following cases have been selected to illustrate the points which we desire to emphasize, and also because they have come under the observation of some of the most competent and well-known life-insurance examiners.

Case I.—Merchant, born 1837. Albuminuria detected May, 1890, but applicant was accepted in June, 1890, after the satisfactory examination of several specimens of urine, the heart and blood vessels having been found to be normal. Died July, 1900, of Bright's disease of two years' standing, according to the report of the attending physician. It may be permitted to say that the disease has existed for some time in most of these cases before becoming grave enough to attract attention.

Case II.—Merchant, born 1852. Examined January, 1883, and found to have albuminuria, a pulse of 108, and a sharp metallic click with both sounds of the heart audible at the apex and transmitted around to the axilla. Re-examined July, 1893, and accepted, as there was then no albuminuria nor indication of heart trouble. The attention of his attending physician was called to the case in December, 1898, and a diagnosis of Bright's disease was made at that time. Died August, 1900.

Case III.—Merchant, born 1851. First examined June 3, 1898, at which time albumin and hyaline casts with a few red-blood cells were found. On June 7, 1898, was considered by another company and accepted, as the urine was found to be normal. This company, on learning the condition found at the first examination investigated the case further on June 28, and again found the urine normal. On February 28, 1900, the applicant once more applied for insurance and was again declined on account of albumin and casts. Still another examination was made December 26, 1900; no casts were found this time, but there was a trace of albumin, and in several specimens of urine examined the specific gravity ranged from 1010 to 1015. Immediately after his first rejection, June 3, 1898, the applicant consulted his medical adviser, who made an examination and, obtaining negative results, merely expressed the opinion that the examination for insurance had taken place at an unfortunate time. The patient died in March, 1903, of chronic nephritis, still attended by the same physician who stated that he first discovered albuminuria and cardiac weakness in September, 1901.

Case IV.—Bank President, born 1849. First applied for insurance in November, 1878, at which

time albumin was found in his urine during a period covering several days, the specific gravity remaining about 1028. In March, 1893, the applicant was again rejected, as traces of albumin were found in samples obtained on five different days, the specific gravity ranging from 1020 to 1022. The heart and blood vessels were found to be normal at both examinations. Died February, 1897, of Bright's disease after a period of unusual excitement and nervous strain.

CASE V.—Capitalist and railroad president, born 1840. Applied May, 1891. Rejected on account of a trace of albumin with a few hyaline casts. The application was for a large amount in several companies, and consequently examinations were made by a number of physicians, who agreed as to the condition of the urine and the normal state of the arteries. There was, however, a division of opinion regarding the heart, some holding that there was an almost inappreciable enlargement. In December, 1895, the urine was found to contain hyalo-granular casts, but the reaction was doubtful in regard to albumin. Another company had issued insurance to this man just previous to this last examination, the applicant assuring the medical directors that he was leading a much less strenuous life and intended to continue doing so. It may be added that at this time the heart and blood vessels were found to be normal in all respects. In May, 1900, the urine was examined chemically and albumin was found. No further examination was made at this time, as there was no formal application. During the summer of 1902 the applicant was reported in the newspapers to be a very sick man, and death occurred in January from chronic nephritis with heart complications.

CASE VI.—Merchant, born 1868. Applied at different times to four companies, which, for the sake of convenience, will be designated by numbers: Company No. 1 declined, in December, 1900, on account of albuminuria, reconsidered and approved in November, 1901, and rejected a second time in May, 1902, as albumin was again found. Company No. 2 discovered albumin and casts in January, 1901, but reconsidered and approved in April, 1902, the urine being found normal. During the preceding month Company No. 3 had rejected the applicant on account of albumin and numerous hyaline casts. The applicant sought insurance from Company No. 4 in March, 1903, and the examiner reported the urine normal chemically and the heart and blood vessels free from any pathological changes. The urine, however, had a specific gravity of 1017. In April another examiner also reported the urine free from albumin, but discovered hyaline and granular casts in two different samples. The latter finding was corroborated by the former examiner a few days later, who also found the specific gravity to be 1012 and 1010 in two specimens. On closer questioning the applicant admitted passing large quantities of urine, and that he had recently been under treatment. A diagnosis of chronic nephritis was made, though circulatory disturbances were absent.

CASE VII.—Bookkeeper, born 1848. Accepted in December, 1882. Allowed policy to lapse and applied for reinstatement October, 1891, at which time albumin was found in two samples of urine. In April, 1892, he was examined again and albumin found to be still present. He then placed himself in charge of a physician, who wrote that the applicant was a healthy man and that the trouble was due to gleet. Died May, 1900, from nephritis, another physician under whose care he had placed himself stating that he had found the health of the patient affected about seven years before.

In these reports of chronic cases terminating fatally, special attention is directed to three points: The intermittence of the albuminuria, the occasional absence of tube-casts, and the frequency of grave kidney disease without apparent disturbance of the circulation.

During the past few years the subject of nucleoalbumin has excited much interest, but the source and nature of this substance is still largely a mystery. In some cases it seems easy to determine the origin, and to conclude that it does not indicate anything more serious than chronic gleet, mild prostatitis, some vesical irritation, or an indiscretion of the previous night. Other cases are common in which hyaline and granular casts are found without serum albumin, and with or without a high-tension pulse. It is possible that even in these instances the nucleoalbumin does not escape through the kidneys, but that some disturbance, such as the gouty or so-called uric-acid condition has caused irritation of the kidney tissues and the rest of the urinary tract as well. This view is, however, open to doubt, the more so because of the fact that nucleoalbumin has been found during eclampsia. Through the courtesy of Dr. Brandreth Symonds we are permitted to refer to two such cases which have come under his notice. The first symptoms noticed in both the cases of threatened eclampsia were nucleoalbumin associated with toxic symptoms in the form of puffiness under the eyelids and dropsy in other parts, headaches, and beginning anæmia. The nucleoalbumin and toxic symptoms increased, and casts appeared, but no albumin. Labor was induced, the nucleoalbumin and toxic symptoms rapidly disappeared, and then, for the first time, serum albumin was noticed. These few remarks in regard to nucleoalbumin have been made simply for the purpose of inciting further observation and investigation of the conditions which give rise to this pathological product, as we are of opinion that these cases are not always to be deemed of slight importance.

The conclusions which may be drawn from these observations are the following:

1. It is impossible to determine whether albuminuria is a premonition of further trouble until the case has been kept under observation for some time.

2. Transient albuminurias are not of serious import unless they recur too frequently.

3. Persistent and even cyclic albuminurias should cause anxiety on the part of the attending physician, who should endeavor to ascertain the cause and take measures for the removal thereof.

4. The earliest indications of Bright's disease will, as a rule, be found in the urine.

5. Careful observation of these cases means frequent examinations of twenty-four-hour specimens of urine for the purpose of finding out the daily quantity, the amount of urea, the specific gravity, and the presence of albumin and casts. The blood vessels and the heart should also receive attention. These observations may have to extend over a period of months or even years.

6. The most frequent causes of albuminuria are excessive eating, over-indulgence in alcoholic drinks, and possibly tobacco, mental and physical stress, and the gouty diathesis.

7. The mortality among albuminuria cases is great, not only because chronic nephritis is often associated with it or may follow later on, but also

on account of poor resistance offered to other diseases.

## THE ART OF INCREASING AND DIMINISHING THE BODILY WEIGHT AT WILL.*

By MAX EINHORN, M.D.,
NEW YORK.
PROFESSOR AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

The physician is frequently confronted with the problem of modifying the bodily weight in one or the other direction. Many chronic maladies are accompanied by considerable loss of weight, and in their enfeebled state the patients are greatly hampered in their battle against disease. If, however, we succeed in putting them into a better general condition, then they are enabled to vigorously combat their troubles. To obtain an increase in weight is therefore here of primary importance.

An excessive bodily weight also leads to disagreeable conditions, occasionally even to disease. Accumulations of fat around the heart and intestines impede the action of these organs. The ponderous body is sometimes too heavy for the legs; laziness results, leading occasionally to fatty degeneration of important muscles, including the heart. In all these cases a reduction of bodily weight must be sought.

It does not appear superfluous, therefore, to discuss the question how to change the bodily weight in one or the other direction.

I.—The principles governing these problems are intimately connected with the physiology of metabolism and must first be briefly considered.

*The Revenues and Expenditures of the Body.*—In the life of every being there is a constant exchange of revenues and expenditures. The revenues of the body consist, as we all know, of food and air, the expenditures of the generation of bodily heat necessary for life and of the work performed (heart action, respiration, glandular activity, muscular work in general).

The value of food is measured by its caloric energy. Heat may be transformed into power and the latter into the former. The mechanical equivalent of one calorie = 425.5 kgm. If the work performed (expressed in kilogrammeters) is known it can be calculated according to the above formula in calories, *i. e.* we can tell exactly how much heat is consumed in the work accomplished. The human organism, however, is not able to convert the entire number of heat units into work. According to Von Noorden[1] the organism requires for a certain amount of work about four times the amount of potential energy; in other words, 75 per cent. of the calories, changed into power, are given off in the form of heat which radiates from the body and is thus lost.

A person performing about 4,000 kgm. work uses, therefore, $\frac{4{,}000}{425.5} \times 4 = 37.6$ calories.

The amount of food for the adult per day has been calculated at about 2,600 calories.

*Read at the annual meeting of the Monroe County Medical Society, at Rochester, N. Y., May 27, 1903.

*Body Equilibrium.*—If the amount of food taken is just sufficient for all demands of the body we have a balancing of bodily weight or bodily equilibrium, *i. e.* the organism neither loses nor gains in weight.

*What Happens When More or Less Food Is Taken?*—Formerly the view prevailed that the more food is supplied to the animal organism the more material it burns up. As a proof of this theory, the fact was adduced that a short time after eating the consumption of oxygen and the elimination of carbonic-acid gas were found to be increased. Speck[2] proved, however, that the increased consumption of oxygen was to be ascribed to the increased activity of the digestive glands, and therefore the theory of augmented combustion of increased nutritive material had to be abandoned. There are numerous proofs that the organism does not burn up food introduced in excess, but rather utilizes it and converts it into fat.

On the other hand, the organism consumes just as much material even when no food is taken, using up its own substance (fat and muscles). In acute inanition the adult usually expends about 2,100 calories, in protracted inanition somewhat less, about 1,700 to 1,900 calories per day. The loss of nitrogen of a healthy fasting man is about 10 to 11 grams daily.

*Work and Rest.*—With increased muscular work, the expenditure is much larger, as is evident from the above. Lavoisier was the first to recognize this important law. Zuntz[3] has distinguished himself in this field by many important investigations. This celebrated savant has determined the following values for the calories expended in the occupations of ordinary life:

"Walking on a level road requires between 0.5–0.6 calories per kgm. and per 1,000 meters, according to the degree of skill in walking[4] of the individual. A man weighing 80 kgm., and traveling 75 meters per minute would therefore use for every 1,000 m. walking about $80 \times 0.55 = 44$ calories, or 3.3 calories every minute, this being about two and one-half times as much as during absolute rest. If there is a 10-per-cent. grade in the road the total amount per 1,000 m. is $44 + 60 = 104$ calories, or $\frac{104 \times 75}{1{,}000} = 7.8$ calories per minute, 468 calories per hour; this is about the limit of what a strong man is able to perform for any length of time.

"On accelerating the gait the consumption increases about 0.0024 calories per 1,000 m for every meter of increased rapidity between 60–100 m. per minute, above 100 m in increased ratio.

"In wheeling, according to Leo Zuntz, the hourly increase of consumption over that of absolute rest for a man weighing 70 kgm. is as follows:

| | |
|---|---|
| Going 9 km. per hour | 183 Cal. |
| Going 15 km. per hour | 313 Cal. |
| Going 22 km. per hour | 571 Cal. |
| Going 9 km. per hour, 3 per cent. grade | 316 Cal. |
| Going 15 km. per hour, and headwind of a velocity of 10 m. p. second | 601 Cal. |

If, for instance, an adult should traverse four English miles (6,436 m.) he would consume $\frac{6{,}436 \times 44}{1{,}000} = 283$ calories.

With increased work, under the same diet, a person in a state of physiological equilibrium must lose in weight; the increased consumption of calories is supplied from the body tissue. On the other hand, under the same conditions (*i. e.* ingestion of the same amount of food), but with marked diminution

of the usual amount of work (rest in bed), an increase of bodily weight must follow.

Expressed in other words, this means that the body normally does not lose any of the food introduced (after deduction of the usual not utilized residue, which almost always represents a constant percentage), and converts all ingested material into energy (heat or power) or unto tissues. In the same manner, every effort of the organism (heat, energy) must be compensated for by calorifacient material, no matter whether it be furnished by the food or by the body itself (in case of abstinence from food).

After these digressions in the realm of physiology let us return to our subject:

II.—An increase of bodily weight is often desirable in conditions of emaciation and leanness.

Leanness is met with, although rarely, in persons who are perfectly healthy. These are usually individuals of a vivacious temperament doing a great deal of work and eating only moderately. Such persons are apt to remain lean, and may reach an advanced old age without gaining or losing.

It is quite different with those frequently occurring cases of emaciation. The latter accompanies chronic diseases of various nature, and usually progresses steadily. These patients lead a miserable life, and are usually unable to resist any intercurrent disease, and though they may live some years, hardly ever reach old age. In the majority of instances they fade away much earlier.

In emaciation, as is evident, it is imperative to counteract it—this, in fact, constituting the main object of treatment. But also the leanness of the healthy, if it is of a high degree, ought to be combated. For these persons are at a great disadvantage as compared with normal people. They have no reserve fat on which they can fall back in time of need. This may be fraught with fatal consequence in supervening acute febrile diseases.

Can leanness and emaciation be successfully combated? This question must be answered in the affirmative. In nearly 90–95 per cent. of all the cases of leanness and emaciation (cancer, of course, excepted), in which I have made an extended trial to raise the bodily weight, I have been successful.

*Increasing the Body Weight.*—If we desire to obtain a rise in bodily weight, we must introduce into the body larger amounts of food and especially nutriments of a high caloric value. Practically we proceed as follows: We inquire minutely, how the patient has recently lived; what kind of food and how much he has taken with every meal. If we find that his diet was one-sided, we must immediately change it; for a diet list excluding many important foodstuffs is always deleterious in the long run. We will therefore permit as great a variety of food as is compatible with the condition of the case.

We then inquire as to the quantity of food ingested. Should the latter be insufficient it must be our aim to prescribe the food in somewhat larger quantities. If the normal amount is taken, we must make the beverages taken with the meals more nutritious. Coffee and tea, for instance, are given diluted one-half with milk and a small addition of cream as well as sugar, or instead of coffee a glass of milk is ordered.

In suitable cases two or three smaller meals, consisting of milk and buttered bread, may be given with advantage.

It is advisable to prescribe the daily amount of butter that should be taken: I usually order a quarter of a pound per day. Butter is a fat easily digested, and on account of its high caloric value especially suitable.

The success of treatment is practically assured, if it is possible to get the individual to take larger amounts of food. We often have to deal with persons whose appetite is very poor. Here, beside the usual remedies we have to make use of the following dietetic means: Bread and vegetables as well as milk and eggs can usually be taken with relish, even if a marked antipathy for meat exists. The addition of olives, lettuce, horseradish, etc., sometimes aids in overcoming this. A glass of cold water stimulates the appetite while eating and induces a larger consumption of food. It is self-understood that we make use of all these suggestions, which beside their dietetic importance contribute to the patient's enjoyment of life, provided no serious contraindications are present.

Outdoor life and moderate exercise (walking, light gymnastics, bowling, etc.) are of great value. The latter stimulates the appetite, and by satisfying it the increased loss of heat through muscular work will not only be compensated, but probably an excess of food will be ingested without trouble. Exercise, furthermore, serves the purpose of stimulating muscular development and of strengthening the body.

By means of a suitable combination of food and exercise, we effect not only an increased formation of adipose but also of muscular tissue and a gain in strength.

III.—The bodily weight should be reduced as soon as there is a surplus of fat, which is displeasing to the eye or mars the harmony of the body.

There are two ways of diminishing the bodily weight: first, diminution of the amount of food taken; secondly, increase of the amount of work performed, or a combination of both.

Karell[6], and after him S. Weir Mitchell,[6] have tried to treat obesity by a restricted milk diet. S. Weir Mitchell says: "Karell has pointed out that on creamless milk diet fat people lose flesh.

"This can be done rapidly and with safety by the following means: The person whose weight we decide to lessen is placed on skimmed milk alone, with the usual precautions, or at once we give skimmed milk with the usual food, and in a week put aside all other diet save milk and all other fluids. When we find what quantity of milk will sustain the weight, we diminish the amount by degrees, until the patient is losing a half pound of weight each day, or less or more, as seems to be well borne. Meanwhile, during the first week or two, rest in bed is enjoined, and later, for a varying period, rest in bed or on a lounge is insisted upon, while at the same time massage is used once or twice a day, and later in the case Swedish movement. At the same time the pulse and weight are observed with care, so that if there be too rapid loss or any sign of feebleness the diet may be increased. In many such cases I allowed daily a moderate amount of beef or chicken or oyster soup—more as a relief to the unpleasantness of a milk diet than for any other reason."

Banting's cure also is based upon a reduction of the amount of calories introduced with the food (nearly exclusively meat diet).

Oertel[7] was the first to call attention to the value of muscular exercise in the treatment of obesity. By a gradual slow increase of work it was found possible to accustom even a weakened heart to greater exertion. Oertel, as is known, recommended for this purpose the climbing of light grades.

Zuntz[8] is of the same opinion, and advises in

treating obesity to utilize muscular activity. In the treatment of obesity we must endeavor to free the body from superfluous fat, without impairing the amount of albuminoid substance (muscles). This can be most easily accomplished if with a moderate but sufficient diet the usual amount of work is slowly increased without augmenting the amount of food consumption. It is more difficult if at the same time that work is increased the amount of food is considerably decreased.

Practically we should proceed as follows: We must determine exactly under what dietary (this must be estimated quantitively in an approximate manner) an individual will remain in a state of bodily equilibrium. If the person has not gained lately, we may take the amount of food that he has been in the habit of consuming as a standard. If, however, he has been gaining on this quantity, we ought to diminish it, allowing, for instance, only one slice of bread instead of two or three, leaving off intermediate meals, etc. The weight of the patient should be controlled every two or three days, or weekly, by the scales. As soon as the amount of food necessary to keep the body in equilibrium has been determined, we must begin slowly to increase his muscular work. He should walk one-half to three-quarters of an hour in addition to his usual work, or ride a wheel, or row or fence or play billiards or golf, or hunt or fish. Gradually the time for exercise may be lengthened or the degree of work intensified; as, for instance, by traversing the same distance in shorter time, when walking, cycling, or rowing. This materially increases the consumption of calories. If we proceed slowly and carefully, we can soon obtain considerable work even from individuals that are weak.

In increasing the work never allow the patient to become exhausted. The accelerated heart action and respiration due to the exertion must return to normal ten minutes after beginning to rest. If this is not the case, the work must be reduced.

IV.—We have seen that by means of suitable diet and muscular work the body weight may be increased or reduced at will. It is also gratifying to note that the increase or reduction of the body substance, if it is advantageous for the organism, will be distributed in a harmonious way, so as not to offend our æsthetic feelings. In a general way, we will be right if we maintain that beauty and health with regard to bodily shape go hand in hand. When an increase in body weight is accompanied by increased beauty it will be found to be of hygienic value. In a similar manner, a decrease of weight bringing out a more harmonious appearance, is certainly also advantageous to health.

The axiom that fat and muscular tissue are evenly distributed when an increase takes place is, however, subject to an exception in the interest of the organism. The disposition of fat is somewhat greater in places where the subjacent muscles are not called into frequent play, whereas the muscles increase to the largest extent in such places where they are called frequently into action. In reducing weight the opposite holds good. The greatest loss in fat occurs in places where the muscles are most exercised and the greatest loss in muscular tissue where muscular activity is small. The advantage of this arrangement is that fat is deposited in such places where it can cause the least harm and muscles where they are of most value. In the disintegration of tissue of course the contrary obtains. Thus the organism watches that everything shall turn out to the best advantage, *i. e.* it makes use of everything (work and food) for its own benefit.

It is a grateful task for the physician to intervene where in consequence of a false mode of life (too much or too little food, too much or too little work) harm may result to the organism. At the same time we must feel great satisfaction in the knowledge that through simple means (diet and muscular work) we are able to effect an improvement or a cure of the harmful conditions present.

## THE PRESENT STATUS OF SUBCONJUNCTIVAL INJECTIONS IN OPHTHALMIC THERAPEUTICS.*

By CHARLES STEDMAN BULL, A.M., M.D.,
NEW YORK.

In the seven or eight years which have elapsed since the introduction of subconjunctival injections into ophthalmic therapeutics, an army of experimenters have published their experience, either for or against the new method of treatment. As in the case of other remedial measures, either medical or surgical, the advantages claimed for the new method have been beyond all reason. The field for its proper employment has been unwisely extended, and the most extravagant predictions have been made as to its future usefulness. As many of these predictions have not been fulfilled, a general feeling of skepticism is beginning to be developed as to the probability of any good results from the use of subconjunctival injections, which is unfortunate. As time elapses, we may expect the method to find its true and reasonable place in ophthalmic therapeutics.

A glance through the literature of the past seven years will show how contradictory has been the evidence offered of the real value of subconjunctival injections, and a careful study of the various papers on the subject will the better enable us to separate the wheat from the chaff.

In 1897 Di Lorenzo and Bajardi experimented with sublimate injections, and independently of each other concluded that they were useless in infectious processes because they showed no antiseptic action.

In the same year Addario experimented with sublimate injections, and reported that they acted very beneficially in infectious iridochorioiditis, especially the acute form, by causing a contraction but not a disappearance of the exudation. Sympathetic ophthalmia required many injections of from ½ to 1 c.cm. of a one-per-cent. solution.

In 1897 Lagrange recommended a one-per-cent. solution of mercuric cyanide in cases of traumatic infectious panophthalmitis, for cutting short the attack.

* Read before the American Ophthalmological Society at its session in Washington, May 13, 1903.

In 1897 Ostwalt advised the injection of iodoform beneath the conjunctiva, and even into the anterior chamber in all cases of infectious disease or of infection after operation.

In 1897 Tornatola and Alessandro advanced the claims of sodium chloride. They stated that the usefulness of these injections depended on the artificially-excited inflammation and cellular activity. But they also stated that they caused great œdema of the cornea and conjunctiva, and hemorrhages into the uveal tract.

In 1897 Zehnder, in an inaugural dissertation, found a four-per-cent. solution of sodium chloride useful in retinitis pigmentosa in improving the vision and widening the field. In detachment of the retina it proved very useful, curing three out of ten cases, and causing an improvement in five more. He also found it useful in all diseases of the uvea in two, four and ten-per-cent. solutions.

In 1897 Frommaget and Laffoy experimented with the cyanide of mercury in 0.10 solution in suppuration of the cornea, and the staphylococci were all killed.

In 1898 Magnani advised injections of a preparation called phospholuteina in ten to twenty-per-cent. solutions for all scrofulous diseases of the eye and claimed great successes.

In 1898 Tornatola reported that sublimate injections of a one-per-cent. solution were a powerful and rapidly acting but painful derivative in corneal processes, iritis and retinitis.

In 1898 Petella recommended sublimate injections of 1-5,000 in all diseases of the uveal tract.

In 1898 Addario reported that the percentage of sublimate found in the aqueous humor after subconjunctival injections was less than 1 in 10,000, and that in this strength its antiseptic value was worthless, and that therefore the drug must act beneficially in some other way.

In 1899 Puccioni published in a monograph his conclusions that in advanced infectious diseases of the eye, no injections of any kind were of any value *alone*. After subconjunctival injections of sublimate, neither sublimate nor metallic mercury could ever be found in the aqueous humor, cornea or other parts of the globe. He found them, however, of value in syphilitic diseases.

In 1899 Ubry and Frézals reported that in their recent experiments with potassium iodide and sodium salicylate, neither of the drugs could be found in the aqueous humor after injection, unless at the same time a large dose were given internally, but when they were dropped into the conjunctival cul-de-sac, they were later found in the aqueous humor.

In 1899 Straub recommended sublimate injections in all cases in which it was necessary to produce a rapid effect.

In 1899 Brunsi reported that sublimate injections were of use only in infectious keratitis.

In 1899 Neunhöfer concluded that the only subconjunctival injections which should be recommended were those of sodium chloride, on account of their power of exciting rapid absorption.

In 1899 Darier in his characteristically enthusiastic way reported that in cases of chorioiditis, especially of the macular region, sublimate and sodium chloride injected beneath the conjunctiva were more valuable than all other methods of treatment.

In 1899 Vogel published the results of his investigations on the entrance of soluble substances into the interior of the eye after subconjunctival injections, which make interesting reading. He did not succeed in finding any K I in the interior of the eye by the usual methods of reaction. In injecting solutions of mercurial salts, he added a certain proportion of sodium chloride and a few drops of dilute hydrochloric acid, so at to avoid the deposits of albuminates in the tissues. He found that when any trace of a mercurial salt was discovered in the aqueous humor, it was always less than 1-100,000, which is much too weak to have any therepeutic effect.

In 1899 Signorino and Cattaneo, independently of each other, reported on the use of subconjunctival sublimate injections. The former found them very serviceable in beginning purulent uveitis, provided the cornea remained intact. If the injections were done early enough, some vision was preserved, and if the purulent process were advanced, panophthalmitis could be prevented. On the other hand, Cattaneo has seen no good result from these sublimate injections in any form of eye disease, and thinks their use should be discontinued.

In 1900 Matussowsky spoke highly of subconjunctival injections of sodium chloride in three-per-cent. solutions, for corneal ulcers, mykotic affections of the cornea, and iritis of various kinds.

In 1900 Morgano came forward with a new substance for injection in infective processes of the cornea and iris, which he called anticeltina. This consists of a derivate of urea with mercury, and contains 43 per cent. of mercury, is soluble in water in 1 to 1,000, does not precipitate albumin, and does not irritate the tissues. He used from 0.5 to 1-per-cent. solutions, injected it warm beneath the conjunctiva, and spoke most highly of its efficacy in shortening the duration of an infective process.

Somewhat later in the same year, Morgano seems to have transferred his faith and devotion to Pohel's "physiological salt-solution," a solution of many ingredients, which is supposed to act by increasing the osmotic pressure of the fluids of the tissues, and represents also a biochemical effect on the inflamed organs and their exudates, provoking in them histobiological and chemical changes which favor their absorption. Morgano goes on to cite the past experiments of Pflueger, Frommaget, Loffoy, Lagrange, Addario, and others to prove the rapid passage into the interior of the eye of certain soluble substances injected beneath the conjunctiva, and especially of such non-irritating salts as Pohel's solution. He claims that these injections always cause an improvement in the inflammatory processes of the internal coats of the eye, especially of the exudative forms. This improvement sometimes begins after the first injection and proceeds rapidly. The vision and color sense improve, and the vitreous clears up. He found the improvement inversely proportional to the state of the disease; that is, the more recent the attack, the greater the improvement. The injections cause no pain or reaction, and may be repeated daily. He prefers a 1.5-per-cent. solution, which should always be fresh and at a temperature of 37° to 38° C. It should be injected slowly, and followed by cold compresses for an hour.

In 1901 Valenti recommended a one-per-cent. sublimate solution, and Angelucci a mixture of sublimate and salt of the same strength, as particularly useful in septic corneal processes and in syphilitic diseases.

In 1901 Stasinski spoke strongly of the very beneficial effect of salt-solutions in all cases of acute chorioiditis, stating that the exudation rapidly disappeared and vision was restored to the normal standard.

In 1901 Pflueger published an article in favor of

injections of a two-per-cent. solution of sodium iodide and sodium chloride in cases of chronic chorioiditis with opacities of the vitreous humor. He, however, combined with the subconjunctival injections puncture of the anterior chamber, which he claims considerably augments the effect. He found that injections of stronger solutions (four to ten per cent. caused severe pain, but were indicated in detachment of the retina.

He subsequently tried another lymphogenous substance, more effective in weak solutions, and at the same time less painful, namely, hetol or sodium cinnamate, in solutions of one to five per cent. He found that this substance produced a leucocytosis and an aseptic inflammation around the foci of disease, with envelopment of these foci by leucocytes. The new formation of embryonic tissue caused absorption of the masses of infiltration, which are replaced by solid connective tissue. He thinks the hetol is especially adapted for tuberculous affections, but believes that all diseases in which artificially produced leucocytosis would favor a cure should respond to this treatment. He claims to have brought about a more than usually rapid healing in corneal herpes, deep corneal ulcers, iridocyclitis, tuberculous uveitis, and scleritis, by injections every second day of from three to five c.cm. of a one-per-cent. hetol solution. The pain caused was very brief and slight, and dressings were unnecessary.

In 1901 Uribe Troncano vaunted the claims of solutions of mercuric cyanide for all cases of exudative inflammation within the eye.

In 1902 Wecker recommended injections of gelatin of 2½ per cent. concentration, carefully sterilized, with a 3 to 5-per-cent. solution of salt for detachment of the retina.

In 1902 Bourgeois reported twelve cases of detachment of the retina in which he injected a concentrated (thirty per cent.) solution of sodium chloride. One case was cured, three cases were markedly improved, and three cases were slightly improved.

An examination of all the papers published on this subject by the various authors quoted, and a careful study of all the cases of all kinds reported, leads irresistibly to at least one conclusion, viz., that the efficiency of these various solutions injected beneath the ocular conjunctiva cannot be ascribed to the increased local acceleration of the lymph-currents, the so-called leucocytosis, nor to the antiseptic action of the remedies employed, since the presence of such processes cannot be demonstrated in the tissues of the eye, following the injections. The chief change seems to be in the composition of the aqueous humor. This is said to become much richer in albuminoids, due to the irritating action of the injected substances upon the blood vessels. This causes congestion of the vessels and an increased transudation of albuminoid substances from the vessels into the aqueous humor. The physiological chemists have taught us that the protective substances of the blood are always to be found in combination with the albuminoids of the blood. Hence coincidental with the increase of serum albumin in the aqueous humor would be the appearance of various protective substances in the same. If subconjunctival injections of sublimate or sodium chloride be made, it will be found shortly afterward that the aqueous humor has become markedly hæmolytic. Hence the action of these subconjunctival injections is to be sought in their local irritating properties.

During the past three years I have employed the method of treatment by subconjunctival injections in various diseases of the eye, including different forms of keratitis, chorioiditis, iridochorioiditis, detachment of the retina, cellulitis of the lids and orbit, and panophthamitis. A number of different solutions were used, sodium chloride, sublimate, mercuric cyanide, and hetol, and of varying strength. I have not been able to determine any important difference in their mode of action or effect between salt-solutions and solutions of mercuric cyanide, so highly extolled by Darier. I have not had the success which Haitz claims in cases of central chorioiditis and recent opacities of the vitreous with a solution of mercuric cyanide, and I have found this solution very painful to the patient, even when cocaine or acoin was added to the solution before injection. The solution used was 1–5,000, with two per cent. of a two-per-cent. salt solution added. The injection of this preparation always caused a great deal of reaction, severe pain, and conjunctival inflammation, and was followed by persistent chemosis and hypersensitiveness of the conjunctiva. Hetol or sodium cinnamate was employed in a one-per-cent. sterilized aqueous solution, of which 0.5 grm. was injected at first every second day, cocaine being first injected. This was used in various corneal affections, herpes, wounds, pannus, interstitial keratitis, and in chorioiditis and scleritis. This solution was less painful than the mercurial preparations and seemed to influence favorably the course of the disease in herpes and interstitial keratitis. It seemed to be of benefit in acute uveitis in hastening the process of absorption. The beneficial effect seemed to come on sooner if the disease were superficial, as in corneal cases. It was apparently of no use in chronic cases, notably failing in scleritis. It was used persistently in two cases of tuberculous disease of the iris and chorioid, but apparently without the slightest effect.

A careful observation of my own cases, in which various solutions were employed, has not been able to convince me that subconjunctival injections bring about any more rapid or favorable results than other methods of treatment which we have hitherto employed for affections of the cornea, uveal tract or retina. In several cases of orbital cellulitis of an infectious character, however, I found that subconjunctival injections of a sublimate solution (1–1,000) did exert a very favorable and unusually rapid effect in hastening the suppurative stage, in reducing the dense infiltration of the orbital cellular tissue, and thus aiding in restoring the circulation to the strangulated parts.

My own conclusions, based on observation of my own cases and a careful study of the literature of the subject, are that all reports of the beneficial effects of subconjunctival injections should be carefully criticised and compared with the results obtained by other methods of treatment before accepting them as of any real value.

---

**Hydriatic Treatment of Sciatica.**—J. B. Cathomas reports the extensive use of hydropathic measures in the treatment of this disease. These measures are multiple and include all of the so-called "water-cure" methods combined with massage and electricity. The most marked results are produced in old cases which have resisted other forms of treatment and in which muscular contractures have become pronounced. Only cases of pure ischiatica are suitable for this treatment, since those which show complications are not only not benefited but frequently become worse. Three sample cases are reported in detail.—*Correspondenz-Blatt für Schweizer Aerzte.*

**Ateleiosis: A Form of Dwarfism.**—Hastings Gilford gives the histories of five cases of this disorder, the name of which is derived from the Greek ἀτελείωσις, signifying "not arriving at perfection." There are two varieties of the affection. In the one there is conspicuous delay of both growth and development up to the onset of puberty. The sexual system then matures, and the development of the body becomes arrested, leaving the individual sexually complete, but in other respects with the proportions and outward appearance of stereotyped childhood. Hence in this variety there is infantilism up to puberty and after that period there is dwarfism only. But in the second variety there is, as a rule, both dwarfism and infantilism throughout the whole of life, for the sexual system never matures, while growth may continue up to the age of thirty or even later. The cases reported by Gilford are all of the second or asexual variety. This is subdivided according as the malady begins in fetal life, in infancy or early childhood, or at some later period of development. The article is fully illustrated and gives measurements and radiograms showing comparisons between the subjects of ateleiosis and normal individuals. The previously reported cases are also reviewed. Ateleiosis should be regarded not as a disease *per se*, but merely as a symptom or condition. It is to development what dwarfism is to growth. As regards the pathology of the condition there is no evidence that the brain, pituitary body, thyroid, pancreas, or any organ is the seat of origin of the disease. We only know that there is defective development of the whole body, and that this is often preceded by hypoplasia of the sexual organs, and is prone to be associated with some developmental anomaly of other parts. But there is no evidence showing to what this abnormal delay of development is due.—*Practitioner.*

**A New Method of Fixation for Movable Kidneys.**—Guiseppe Ruggi formulates the following rules for the technique of nephropexy: (1) The displaced organ must be returned to a relatively normal position. (2) It must be affixed to the thoracic framework in such a way as to be protected by it. (3) The kidney must not suffer any gross or microscopic trauma as the result of the operation. (4) The operation must be conducted with all the precautions necessary to ensure primary union. (5) The kidney must be immobilized in its new position so securely that no tension on its vessels or nerves is possible. The author has devised a method which he believes fulfils the above requirements and is superior to others. The incision used is the costo-lumbar one of Hahn, prolonged downward somewhat to gain room. When the pararenal tissue is reached it is removed, as is also a portion of the fatty capsule, special attention being paid to checking hemorrhage. The kidney is forced up into the wound, and its capsule split along the dorsum. This is peeled back from either side and the two free portions are twisted on themselves so as to form two pedicles, one on either side. These are transfixed with a suture, and form two stalks from which the organ hangs suspended as in a hammock. The sutures are then carried up under the twelfth rib, and are tied in the intercostal space, their tensions pulling the kidney up into position behind the rib. In cases in which the condition is of mild type it is sufficient to decorticate and form a stalk only on one side, but when the displacement is more serious the double suture is to be preferred.—*Centralblatt für Chirurgie.*

**The Statistics of Ethylchloride Narcosis.**—George Lotheissen, who was the first public sponsor of this agent as a general anæsthetic discusses the various deaths that have been ascribed to it with the object of clearing the good name of the drug. Six deaths have been reported as due to it, and the author considers each in detail. In four death did not occur until from an hour and a quarter to seven days after the operation, and there were enough exterior factors to exonerate the anæsthetic from blame. Of the two others, one occurred in a diphtheritic child which was being tracheotomized for laryngeal obstruction, and here, also, the author thinks it is hardly fair to accuse the ethylchloride. The last case is a *bona fide* anæsthetic death, the patient being a middle aged alcoholic man, whose arteries were sclerotic and whose heart muscle was degenerated. In April, 1902, 16,000 ethylchloride anæsthesias had been reported and since then no doubt at least another 1,000 have been added. This makes one death to 17,000 cases, or even adding the second doubtful case 1 in 8,500, a mortality lower than that of ether. The author therefore continues his advocacy of the anæsthetic, and considers it a safe and valuable adjunct to the surgeon's materia medica.—*Centralblatt für Chirurgie.*

**Some Remote Effects of Eye-strain.**—George H. Thomas says that as a result of increased study on the part of oculists, very many ailments are described as having been relieved by eye treatment. Among them are cases of neurasthenia, hysteria, melancholia, nervous dyspepsia, vertigo, insomnia, migraine, epilepsy, chorea, hay-fever, car-sickness, and sea sickness; with less definite symptoms of anorexia, faintness, nervous irritability, weariness, mental confusion, stammering, and even chronic constipation, nocturnal enuresis, and dysmenorrhœa. The author's notion about the matter is that the eye-strain does not produce these symptoms directly or reflexly, as is commonly maintained, but that it produces a greater or less degree of general nervous debility, which, with other less marked though perhaps more definitely localizing causes, produces symptoms sometimes in the brain, the peripheral nerves, the stomach, or some other organ. A chain of ills with eye-strain acting as the connecting link is produced, or a morbid structure with eye-strain as the corner-stone, which must be removed to establish health.—*Northwestern Lancet.*

**Dislocation of One-half of the Frontal Bone During Parturition.**—Stewart Le Roy McCurdy reports this case, which is plainly a dislocation of the right half of the frontal bone. The force producing this rare dislocation was applied during parturition. Ossification of the frontal bone begins at about the eighth fetal week and is not completed for several years after birth. The metopic suture between the halves of the median line sometimes remains open through life. At birth there is nothing but membranous attachment throughout the circumference of the frontal bone, so that force applied to the head as it passes through the pelvis straight in lateral frontal presentation could very readily result in just such an accident. A spring band was used about the head with a pressure pad resting upon the frontal eminence. By gradually increasing the force, it was hoped to produce some benefit. But little was accomplished. The child is, however, in every way normal. The brain has conformed itself to the new cranial wall so well that its functions are performed perfectly.—*Pediatrics.*

**Tetanus Caused by Ascarides.**—Jérôme Buchholz reports a violent, typical case of tetanus, without prodrome and without other determinable cause, in a young girl of seventeen years. After the ingestion of the first santonin powder with calomel (gr. 0.10 of each), the cramps ceased, and after four powders, the patient evacuated sixteen ascarides worms of unusual length and size. Recovery rapidly followed. The parasite was not examined to see whether it was the ordinary ascaric lumbricoides, or the a. megalocephala of the horse and cow. Some years later the writer was called to the same patient. There were the same symptoms, but less marked. The same powders were given with the same results. The writer believes to have proved thus the existence of a form of vermicular cramp, purely tetanic, even outside of the limits of childhood. In the literature he has found this cause indicated only by E. Rose, in his article on tetanus.—*Norsk Magazin for Lægevidenskaben.*

## THE THERAPEUTIC VALUE OF ALCOHOL.

THE drink question is of so vast importance in these days that it is always cropping up as a subject for discussion among scientific men in all parts of the world. As yet there is no decided unanimity of opinion as to whether alcohol is, under certain circumstances, of great therapeutic value or not, nevertheless the views of medical men have greatly changed regarding this matter. Time was when it was altogether in the way of ordinary routine practise to prescribe alcoholic beverages to almost every sick person, and especially during the stages of convalescence, for the purpose of aiding indigestion, acting as a tonic or as a useful stimulant. At the present time such a custom is severely frowned upon, and many scientific men of the very first rank, and whose opinions carry great weight, denounce alcohol as a poison regarded from any conceivable standpoint, and declare that the human race would be vastly better in all respects if strong drink were never used. Of this band, and a doughty champion of total abstinence, is Professor G. Sims Woodhead.

At a meeting of the Islington Medical Society which took place recently, and which was reported in the *Lancet*, June 13, the medical problems of alcoholism were discussed at length, and the whole question was once again carefully gone over. Professor Woodhead opened the discussion. He argued that alcohol, as a poison, has a more far reaching effect than by its action on the liver alone, although that organ has always been looked upon as the chief sufferer. Considering its other effects, he was of the opinion that it appeared to act in two ways. He said that "First, it acted upon the protoplasm of the different cells of the body, causing in many cases a rapid degeneration, the evidence of which was manifested by the presence of fat in the cells of various organs, by cloudy swelling, by the disappearance of Nissi's granules, or by the stunting and clubbing of the turglets on the long processes of the nerve cells and the moniliform thickening of these processes. At the same time the poison, acting on the connective tissue cells in the immediate neighborhood, all much less highly developed and, therefore, more readily stimulated to proliferation, caused an increase of these cells near the seat of degeneration. In very chronic cases these connective tissue changes appeared to be primary, but he thought that although they were the changes that were most prominent and permanent, they were, in most cases, quite secondary to, and dependent to some extent upon, the more important degenerative changes first mentioned. This might, however, be a primary change, especially when occurring in the walls of the blood vessels or in tissues richly supplied with lymphatics. In connection with changes in this latter position he pointed out that alcohol not only impaired function in one direction, it had a direct effect in bringing about a retention of the waste products of the body in the tissues themselves, and in the fluids in which these tissues were bathed. These waste products being of a highly poisonous nature, acted along with the alcohol in increasing the extent and severity of the degenerative and irritant processes of which mention has been made.

In conclusion, Professor Woodhead quoted the experiments of Kurz and Kraepelin to show that the foundations of chronic alcoholism might be laid sooner than is generally supposed. They say: "A single dose of 80 grams of alcohol (2½ ozs.) does not pass off quickly and perfectly, but leaves behind an after-effect which lasts more than twenty-four hours. If this dose is repeated in twenty-four hours, a gradual increase of effect is produced, which we must designate as the commencement of chronic alcoholism, and this is already very evident after twelve days' action by a depreciation of faculty to the extent of 25-40 per cent.

Other speakers who joined in the discussion—and especially Dr. Alexander Morison—did not altogether agree with the extreme views propounded by Professor Woodhead as to the pernicious effects of alcohol under all circumstances, but pointed out that it was not as a stimulant to the digestive process that alcohol found its most valuable application in medicine. It was as seriously combating threatened cardiac failure that alcohol found its most useful applications in medicine, in serious and sudden emergencies, in the prolonged strain of exhausting diseases, and in the shock either of mental distress or of severe pain in the heart itself or in some other region reacting on the heart.

Dr. Anderson also somewhat deprecated the vigor and questioned the validity of the expressed opinions of the extremists as to the harmfulness of alcohol at any time or under any circumstances, and considered that alcohol in carefully regulated doses acted as a food and as a producer of force in the malnutrition and malassimilation of chronic disease, and in the exhaustion of acute disease.

Perhaps the truth lies somewhere between the views of those who declare that alcohol can never be anything but a poison, and of the ones who think that it possesses decided therapeutic value. The evils which proceed from its abuse far outweigh its good effects, but this fact does not prove the point that under no conditions does the judicious therapeutic use of alcohol produce beneficial results.

## THE SANITARY CONDITION OF MANILA.

WHILE the medical profession and general public are well acquainted with the remarkable sanitary results achieved in Havana during its occupation by American troops, the sanitary progress in Manila under American control has largely been disregarded. With newspaper reports relative to cholera, plague, and smallpox in the Philippines, there has been a tendency to consider Manila as a hopeless pest-hole, beyond redemption, in which a white man cannot live. The letter of transmittal

which accompanies the report of the Manila Board of Health for the month of March, 1903, is therefore of special interest, as it presents statistically the results of the sanitary improvements which have been brought about since the establishment of a board of health by the military authorities four years ago.

Comparing the death rates in Manila for the first three months of each of the last four years, and figuring for each month on a basis of the deaths which would occur at the existing rate in each 1,000 population for one year, the statistics are as follows:

| MONTH | 1900 ANNUAL DEATH RATE PER 1,000 | 1901 ANNUAL DEATH RATE PER 1,000 | 1902 ANNUAL DEATH RATE PER 1,000 | 1903 ANNUAL DEATH RATE PER 1,000 |
|---|---|---|---|---|
| January..... | 50.65 | 36.22 | 30.16 | 23.46 |
| February..... | 47.08 | 36.69 | 30.81 | 22.05 |
| March..... | 42.67 | 42.67 | 30.02 | 21.01 |
| Average annual death rate for period compared... | 46.80 | 38.19 | 30.33 | 22.17 |

These figures show that so far, during the present year, the death rate in Manila is less than half what it was during the same period four years ago. Based on present estimates of population, and reducing these rates to gross figures, the number of lives which may be expected to be saved in the city of Manila during the year 1903, judging from the three months the statistics for which have already reached us, as compared with the year 1900, should amount to no less than 7,442.

During the first quarter of the present year, the death rate has been reduced 27 per cent. below the rate existing for the same period twelve months previously. This latest improvement has been accomplished in spite of the fact that cholera and plague had both previously gained a foothold in the islands, and that the existence of a largely unvaccinated population in the provinces meant a constant introduction into Manila of the infection of smallpox. Cases of plague, cholera, and smallpox have occurred in each of the above months of the present year, but the precautions taken by the Board of Health were able to prevent any epidemic outbreak as a result of these cases.

The report calls attention to the fact that the present annual death rate of Manila, 22.17 per 1,000, as based on the statistics for the first quarter of this year, is lower than that of many cities, situated in the United States and elsewhere, which are not commonly regarded as unhealthful. Among these may be mentioned, for the year 1900, Washington, 22.80; New Orleans, 24.74; Altanta, 23.01; Memphis, 25.10; San Antonio, 27.01; Charleston, S. C., 34.94; Liverpool, England, for the year 1899, 24.33; and Honolulu, Hawaii, for the year 1902, 25.59. The present rate is lower than that for Naples, Marseilles, and Madrid, and nearly as low as that for San Francisco, Boston, Baltimore, Jersey City, Havana, and other cities.

The report states that the sanitary results attained in the past four years, under the regular and volunteer medical officers of the army who have been in charge of the Board of Health since its establishment, have been attained despite the naturally insalubrious site of Manila and its total lack of sanitation under the former sovereignty; which—from the level site interfering with drainage, the many foul canals ramifying through the city, the absence of any sewerage system, and the existence of an impure and insufficient water supply and many old, unhealthful habitations—have created sanitary problems of the greatest difficulty. The Board of Health has, therefore, been unable to turn previously existing methods and conditions to sanitary advantage; and has found it necessary not only to develop entirely new plans of improvement, but at the same time to remedy the results of conditions inherited from the Spanish administration. Further, the mixed character of the inhabitants, with their divers languages, prejudices, superstitions, and largely primitive habits of life, has also been a constant obstacle to sanitary progress. Thus it may be mentioned that circulars of the Board of Health for Manila are necessarily published in the English, Spanish, Tagalog, and Chinese languages. Following the putting down of the insurrection, there has also been a strong tendency toward passive resistance by the natives to the efforts of the American authorities.

The Manila Board of Health at present consists of Dr. E. C. Carter, U. S. Army, Commissioner; Dr. E. L. Munson, U. S. Army, Assistant; Dr. T. R. Marshall, late U. S. Vols., Chief Health Inspector; Dr. P. C. Freer, Superintendent of Laboratories, and Mr. H. D. Osgood, Sanitary Engineer. These gentlemen, and their predecessors, should be congratulated on the results of their labors, which have steadily changed Manila from a plague spot of the Orient into a city in which the expectation of life is at least as good as in any of our chief southern cities having a large colored population, and which already closely approximates that in any of our large communities. The sanitary results obtained are little short of marvelous, considering the obstacles encountered, and again demonstrate the fact that an intelligent American sanitary administration can remove dangers which were formerly considered to be inevitable concomitants to life in the tropics. There is reason for much justifiable pride in what has been accomplished by American sanitarians in Manila; and with time, money, and more settled conditions there is every reason to anticipate that the results obtained in the past will be improved upon in the future.

## THE HISTORY OF LEPROSY.

In a recent issue of the *British Quarterly Review* is an excellent description of leprosy written by George Pernet, based upon the best recent books published on the subject, and the report of the last British Commission.

The disease is not limited to tropical and subtropical regions, as many suppose. It exists in Greenland, Norway, the Aleution Peninsular, and Kamtschatka. Nor is Norway the only point in Europe affected. In Russia the disease is endemic in various districts, it also occurs in Sweden and Finland and there are many infected areas in other countries, as Spain, Portugal, Italy, Sicily, Roumania, the Balkan Peninsula, Greece, and the islands of the Adriatic and the Grecian Archipelago. In Asia—the home of the disease—lepers swarm among the huge populations of India and China. There are infected areas in Siberia, and in Southern Asia the

Dutch East Indies may be mentioned as containing many afflicted with the malady. A large number of lepers are also found in Asia Minor, Palestine, Persia, Cuba, Philippine and Hawaiian Islands, Fiji and Madagascar. Leprosy is pretty widely distributed throughout Africa, is prevalent to a greater or less degree in most parts of South America, and is known in certain districts in the United States, notably in Louisiana. Indeed, leprosy is practically present all over the world, and is not the least of the white man's burdens.

The disease is of the greatest antiquity. It is probable that leprosy has existed almost from time immemorial in China, the Province of Kwang-tung has been termed the cradle of leprosy. It is supposed to have existed in Egypt some thousand years before Christ, while Greece appears to have been the first European country to suffer.

Referring to the leprosy of the Bible, the article in the *Quarterly* throws doubt on the belief that the disease was really leprosy. It is by no means certain that the word Caraath means true leprosy. "The leper white as snow" was suffering more probably from leucoderma, which is not a contagious affection at all; although it is difficult to understand why such minute directions for disinfection and segregation should have been given in the Old Testament in the case of a non-contagious disease. In Western India two kinds of leprosy are recognized. One is called black leprosy, or, in Marathi, rak tapiti; the other, white leprosy, goes by the name Kod. The former is true leprosy, but the latter is not and corresponds, no doubt, to leucoderma.

According to the late Sir Richard Burton, leprosy was regarded by Moslems as a scriptural malady on account of its prevalence among the Israelites, who, Manetho tells us, were expelled from Egypt because they infected and polluted the population. The Arabs distinguish two kinds of leprosy, bahak or baras, the common or white, and juzam, the black or true leprosy.

The statement frequently made that it was imported into Eastern Europe by the Crusaders is incorrect, as the disease prevailed in Provence, Italy, and other parts long before. The Saracenic invasion of Spain and Sicily probably led to the spread of leprosy in Western Europe. Although it is certain that leprosy existed in Europe before the Crusades, yet it cannot be doubted that there was a recrudescence of the disease and an increase in the number of lepers at about that period. Many leper-houses were built at various times in the Middle Ages in England. It has been asserted that the leper-hospital at Nottingham, England, was established in 625, but this is not generally admitted, many writers being of the opinion that the first foundation of the kind did not take place until the eleventh century. Some writers of the seventeenth century have distinctly expressed the opinion that many of the inmates of leper-houses in Bavaria and Holland, for instance, were not lepers, but suffering from psora perversa and lepra græcorum.

About the end of the fifteenth century leprosy was subsiding in Europe, and by the sixteenth it had lost its endemic character. As to the causes which led to its disappearance, the writer in the *Quarterly* thinks that it is only reasonable to suppose that more than one factor played a part in the eradication of the disease. It cannot be doubted that segregation, such as it was, was helpful in this direction, and it is just as certain that other factors, such as improved diet, housing, and clothing, have contributed to the rooting out of leprosy in England; but were overcrowding, dirt, and bad food capable of producing the disease *de novo*, it would still be flourishing in that country. With regard to prophylaxis, the writer is of the opinion that where the disease is endemic, the isolation of lepers in special hospitals or settlements is the best way of dealing with the malady, and the article ends with this statement: "There can be no doubt that those countries which are open to the immigration of large numbers of natives from leprous regions and areas are in danger either of becoming infected or of the disease obtaining a permanent footing and becoming more prevalent."

It is somewhat curious that although leprosy is one of the oldest diseases known, that divergent views still exist as to its contagiousness. The majority of those experienced in the disease hold that it is contagious, but there are some very eminent physicians who assert that if contagious at all, it is in so slight a degree and under such exceptional circumstances, that the matter is scarcely worth consideration.

## MEDICAL RECIPROCITY.

THE demand for medical reciprocity between the various States of the Union increases in directness every year. It certainly seems an anomalous condition of affairs that a man who has gained a diploma in one State should not be permitted to practise medicine in another State, possibly the next. Nevertheless, there can be little or no alteration until all, or at any rate some of, the States have decided upon a uniform standard of medical education. It would be manifestly unjust, not to say absurd, for a State which has adopted a high standard of medical education to admit—without a searching test—medical graduates of a State in which the standard of medical education is not upon an equal plane. Of course, it will be only a question of time, when a uniform standard of medical education will be in force throughout the United States; but it may be long before this hoped-for event comes to pass.

In the meantime there would seem to be no reason why several States in which the regulations admitting to the degree of doctor of medicine are similar, should not have medical reciprocity between them. Wisconsin, Indiana, Michigan, Ohio, Iowa, and Kansas have recently formed what is termed "The American Confederation of Reciprocating Examining and Licensing Medical Boards." This body says, in a circular, just issued representing their views, "that, for the purpose of establishing medical reciprocity among the States comprising it, the American Confederation of Reciprocating Examining and Licensing Medical Boards does hereby agree to the following propositions as a basis of reciprocal medical registration:

(*a*) That as a prequisite to reciprocal registration, the applicant therefor shall file in the office of the Board of State of which he is a licentiate such evidence as will enable the said board to certify that he is of good moral and professional character.

(*b*) That a certificate of registration showing that

an examination has been made by the proper board of any State, on which an average grade of not less than 75 per cent. was awarded, the holder thereof having been at the time of said examination the legal possessor of a diploma from a medical college in good standing in the State where reciprocal registration is sought, may be accepted, in lieu of examination, as evidence of qualification. Provided that, in case the scope of the said examination was less than that prescribed by the State in which registration is sought, the applicant may be required to submit to a supplemental examination by the board thereof in such subjects as have not been covered.

(*c*) That a certificate of registration, or license, issued by the proper board of any State, may be accepted as evidence of qualification for reciprocal registration in any other State. Provided that the holder thereof was, at the time of such registration, the legal possessor of a diploma issued by a medical college in good standing in the State in which reciprocal registration is sought, and that the date thereof was prior to the legal requirement of the examination test in such State.

The foregoing qualifications appear to form a fair basis for reciprocal medical legislation, and the plan proposed by the six Western States is to be commended to the consideration of other States in which like conditions prevail. The scheme, moreover, is the "thin edge of the wedge" inserted into the present unsatisfactory system of medical education in the United States. In the behoof of the medical profession generally it would be well if a uniform high standard of medical education were adopted in every State. Reciprocity would then come as a matter of course, a recognized standard would be established and the status of the American medical graduate would be at once satisfactorily raised.

## Evils of the County Jail System.

Many of the county jails throughout the United States are notoriously bad, and according to an article in the New York *Tribune*, June 28, those of New York State are amongst the worst. It is stated in the article referred to, that the system of county jails in the State is, on the whole, as unimproved and defective to-day as it was fifty years ago. It is true that some new jails have been built and the prisoners are better fed, but no further advance toward improvement has been made. With regard to the sanitary features of the jail buildings themselves, it will be better understood what these must be, when the fact is stated that not a few of them have been in use continuously as jails for more than one hundred years, while one of them even was built before the Revolution. A description of one of these old jails will give a good idea of the sanitary conditions of such buildings. The writer in the *Tribune* refers thus to one of the worst: "It is hard to say which is the worst jail in the State, but the one which dishonors Cattaraugus County has the blackest record on the Albany books. It is a brick house of two stories, and the jail and sheriff's quarters are dovetailed in. The jail occupies half of 37x62 feet. There is neither cellar, basement, nor other air space under it, and the plumbing is most defective. The cells, even to the bars, are of wood, and often filthy with vermin. The interstices are full of dirt and germs. The stone floor is badly broken, and there is always considerable seepage after flushing. The drainage to a cesspool is defective, and usually clogged most of the winter. The water backs up to the floor of the jail, and it is necessary to keep a fire going even in summer to make it habitable. The jail has no bath, no hospital cell, no separate department for women, witnesses, or debtors. Besides, it is a tinder-box, and for sickening odor it has every other jail in the State beaten by many degrees." The overcrowding and herding together of the prisoners is not only to be strongly condemned on the score of decency, but is a fruitful means of spreading disease, in this way being a source of danger to the community at large. Sanitary prisons and jails should be in all States of the country, and New York State, in virtue of her foremost position, should lead the way in this most necessary reform.

## Care of Invalids on Board Ship.

There was a time when most physicians were frequently wont to recommend a sea voyage as an excellent means of recuperation after severe illnesses of a certain nature. Some doctors invariably advised patients suffering from pulmonary tuberculosis in its earlier stages to try the tonic effects of a long sea trip. Of late years a considerable amount of scepticism seems to have arisen amongst medical men with regard to the benefit to health to be derived from traveling on the sea. The fact has been pointed out that sea voyages—putting on one side the question of seasickness—affect different persons in different ways. Some are benefited while others are injured in health. Undoubtedly, the discomforts with which an invalid has to contend when on the sea, the lack of facilities for feeding, nursing, and caring for him generally, are among the principal reasons that he does not make satisfactory progress. Thus it has come to pass that physicians are not so well disposed to sea voyages for invalids as they formerly were.

There is, however, a class of sick persons who are compelled *nolens volens* to take a sea voyage. Europeans who have been living in the Tropics and have there broken down in health are the class to which reference is made.

The *Journal of Tropical Medicine*, June 15, has an article on this matter in which, after bewailing the unhappy lot of the sick person ordered home from the Tropics, the writer asks if it is not possible to alleviate in some measure his unenviable and, in many cases, dangerous position when on board ship. The writer then puts in a good word for the ship doctor and proceeds to discuss the question of nursing on vessels at sea. It is obvious that the nurse is a most important person on a ship which carries invalids—in fact, a good nurse is almost as necessary as the doctor. Therefore on such a ship a trained nurse should be carried. In the words of the article "a nurse is, and must in future become, an essential part of a ship's company, and, moreover, the nurse in charge of patients from the Tropics, should have had experience of tropical ailments, and no nurse should be employed who cannot show by her certificates that she has had such training. . . . There is a movement in Great Britain in the direction of insisting upon trained nurses being carried on passenger ships."

The plan advocated in the *Journal of Tropical Medicine* is a good one, and the whole question of transporting invalids from the Tropics to their native land must appeal with special force to Americans. The United States has now far away tropical possessions from which it may be anticipated many must year by year return home broken down in health. It is fitting that these should be enabled to make

the voyage with all the care and attention possible. It might then be well for the Government of this country to insist that passenger vessels plying to and from the Philippine Islands should carry nurses trained in the treatment of tropical maladies.

### Increase of Insanity in the New England States.

Dr. G. Adler Blumer, as President of the American Medico-Psychological Association, which held its annual meeting at Washington, D. C., in May, delivered an address on the increase of insanity. He referred largely to statistics which Mr. F. B. Sanborn had prepared for his report to the National Conference of Charities and Correction held in Atlanta. The report refers to New England only. A study of Mr. Sanborn's report would seem to leave no loophole for doubting that the insane are increasing in New England beyond the natural increase of the population, notwithstanding the well-known fact that statistics are not at all times entirely reliable. "The census enumeration, whether of federal or State direction, is," says Dr. Blumer, "notoriously untrustworthy in this matter of the insane. In Maine the federal census of 1880 gave 1,542 insane in a population of 648,936; but ten years earlier it gave only 792 in one of 625,000, and ten years later it gave 1,299 in one of 661,000. Sanborn takes the very moderate estimate of 1,400 at present, in a population of 661,000, although his own judgment is that the true number exceeds 1,600. There were under asylum treatment in 1901, when the new institution in Bangor was opened, 785 at the old Augusta hospital; at present, after an interval of nineteen months, there are 865 in the two asylums. Thus we have a gain of asylum cases of about 100 in two years, or at the rate of 50, or more than 6 per cent. a year; and, though the actual gain in the whole State must have been less—the opening of a new asylum always increasing the new commitments beyond the average, it is evident to Mr. Sanborn that allowance must be made in Maine for a gain of at least 2 per cent. a year. Yet Maine's total population has not shown a gain of 12 per cent. in thirty years." Estimates made by Mr. Sanborn as to the number of insane in the New England States are as follows: Maine, 1,400, perhaps 1,600; New Hampshire, 900, perhaps 1,200; Vermont, 1,200, perhaps 1,200; Massachusetts, 11,000, perhaps 11,000; Rhode Island 1,150, perhaps 1,200; Connecticut, 3,250, perhaps 3,300. In all New England, 18,900, perhaps 19,500 in a population of about 5,800,000, or 1 insane person to every 307 inhabitants. From all parts of the world the news comes that insanity is on the increase, and while statistics bearing on the matter must be taken with the proverbial grain of salt, the evidence is too strong that the number of insane persons grows larger year by year, to be disregarded as an idle tale or as a gross exaggeration of the true facts of the case. Indeed, the increase of insanity is a dread actuality which has to be looked squarely in the face and, so far as is possible, measures devised to check its further spread.

### The Cure of Consumption.

An article with this title appeared in the *Pall Mall Magazine* for June. The writer gives a minute description of the means used for treating pulmonary tuberculosis in a Scotch sanitarium. In his own case he states that he was cured of phthisis by closely following the regulations laid down for the treatment of patients. As in all sanitariums for consumptives, plenty of fresh air is the principle upon which the treatment is based. The writer, however, disagrees with the plan of feeding advocated in an article entitled "Cry of the Consumptives," published in the *Nineteenth Century*, January, 1899, which has since become famous. Referring to this article he says, "The burden of that thesis amounted to this, that every patient suffering from consumption, who, placed under open-air conditions, drinks three pints of milk and eats six ounces of bread, and three ounces of butter daily, loses his cough within fourteen days." The writer says that for him open-air treatment means something more than an unsupervised life spent in the open air. It means (1) That the patient shall breathe nothing but pure air throughout the whole twenty-four hours of the day. (2) That the diet shall be carefully adapted to each individual case, and that as regards amount it shall not be roughly guessed, but shall be carefully calculated upon a basis of the patient's body weight, and its modification regulated by scientific principles. The assertion that three pints of milk are exactly suitable to every case of phthisis, is alike at variance with the laws of physiology and the teaching of daily experience. (3) It includes the daily and hourly supervision of a skilled and experienced mind—one qualified by training in the schools of medicine, and in the wider arena of life, to deal with the various physical and mental phases of the disease as they present themselves. (4) It requires particularly skilled experience to guide aright the exercise that should be taken. (5) Above all, it means the inclusion of every agent which medical science can bring to bear on the case to increase the resistance of the individual, and to lessen the virulence of the bacillus—be it high frequency treatment, *x*-rays, hydropathy, or therapeutics. When these elements can be secured under good climatic conditions, then consumption, in a large proportion of cases, becomes curable. The foregoing are the views of a layman, who claims to have been cured of pulmonary tuberculosis by the treatment which he has described. Perhaps he lays rather too much stress upon the importance of using all the agents which medical science can bring to bear on cases of consumption, for, after all, it is the fresh air, suitable diet, and a judicious mode of living which are the chief factors in curing or arresting the disease. So far as feeding is concerned, the writer is correct in saying that it is of no benefit to patients to lay down a hard and fast rule as to the quantity and quality of food for all alike. Each person must be considered individually, and the diet regulated accordingly.

### Harriman University, Tennessee.

A striking example of the manner in which degrees are given out by some so-called universities in the United States has recently been supplied in England. A libel action was brought against a journal named the *Christian World* for making disparaging reflections concerning degrees that a Mr. Garnett had obtained at "Harriman University," Tennessee. In the cross-examination of the plaintiff, the fact was elicited that "Harriman University" exists after a fashion—that is to say, that some part of its buildings are in use as a school for boys and girls. The institution also can boast of possessing a chancellor, or rather, it would seem, the chancellor owns the university, for this dignitary conferred on Mr. Garnett the degrees of B.A., M.A., and D.D.—the entire collection costing about $80—and in addition was so obliging as to offer to supplement this imposing row of letters by the unique degree of S.T.D. (Sacra Theologia Doctoris) free of charge. The chancellor likewise forwarded with this last degree the following letter: "I have so arranged

your name as to cause my books to show that your degree has been earned, and it will come *pro merito* and not *pro honoris*." Mr. Garnett, by the way, did not go to Harriman for his examination, but underwent this test at Ocean Grove and Philadelphia. It is stated that no medical degrees have been granted at Harriman University, but nevertheless, it has professors of domestic science and astronomy, the latter of whom, when not engaged in his professional duties, follows the more plebian calling of dentist.

## News of the Week.

**Dr. John H. Gibbon** has been elected surgeon at the Pennsylvania Hospital in Philadelphia, in succession to the late Dr. Thomas G. Morton.

**Dr. Allen J. Smith,** at present professor of pathology in the University of Texas, has been elected professor of pathology in the medical department of the University of Pennsylvania, in succession to Dr. Simon Flexner, who assumes the direction of the Rockefeller Institute.

**Increase in Smallpox in Philadelphia.**—Thirty-nine new cases of smallpox were reported to the Philadelphia Bureau of Health for the week ended July 11, with ten deaths. This is the largest number of cases reported for one week during the present outbreak. Vigorous measures, by means of vaccination and disinfection, have been instituted to limit the spread of the epidemic.

**Yellow-fever Regulations at Havana.**—When a transient vessel arrives at Havana with a case of yellow fever on board, the patient is taken directly to Las Animas Hospital. The immune passengers are set free; the non-immunes are taken to Triscornia station for five days; the vessel is disinfected for mosquitos with formalin or sulphur; and a guard is placed on board until the vessel is ready to go to New York. Shoulda staying non-infected vessel come to Havana, the passengers are treated as above, the crew are kept aboard; the vessel is disinfected. She is not detained if five days in transit, but is detained if less than five days. A guard is placed on board. Should a staying infected vessel come to Havana, the immunes are set free; the non-immunes are sent to Triscornia; the patient with fever is sent to Las Animas direct; the crew is kept five days on board; the vessel is disinfected; she is detained five days in the bay from the completion of the disinfection. In short, immunes are never detained under any circumstances, even those coming on actually infected vessels. Non-immunes from all kinds of vessels are sent to the detention station of Triscornia, where they are detained five days, except those who have come on a vessel which has anchored in the harbor at the port of departure. When a case of yellow fever is found on board the patient is sent direct to Las Animas Hospital. No transient vessel is disinfected unless it has had a case of yellow fever on board. Triscornia is an observation station across the bay, to which are sent non-immune passengers from vessels from infected ports. Immigrants are sent there until they find employment in the city or on the island. Mariel is a quarantine-detention station situated on the coast about twenty miles from Havana. All passengers are sent there from vessels arriving with a case of smallpox or contagious disease other than yellow fever.—*Public Health Reports.*

**Bordeaux Clinic of Diseases of the Larynx, Nose, and Ear.**—The Medical Faculty of Bordeaux, France, has decided to open the courses organized in the special services to medical graduates, French or foreign, upon the payment of fifty francs a term. The course on laryngology, otology, and rhinology, under the direction of Dr. Moure, is held from 9 to 11 o'clock in the morning on Monday, Tuesday, Thursday, and Friday. Saturday is devoted to operations. The course comprises clinical instruction and instruction in the technique of examination and operation.

**Report of the German Tuberculosis Commission.**—At a meeting of the Berlin Medical Society on July 8, Professor Kossel of the Imperial Health Office presented a preliminary report on the results of the experiments of the tuberculosis commission in infecting calves with human tuberculosis. The commission's investigations covered three forms of introducing tuberculosis bacilli in calves: First, subcutaneous injection; second, in food, and, third, by inhalation. The preliminary report was on the results of the first form of inoculation only. The inoculations were not made directly from the human subject, but merely with cultures of the humanized form of tubercle bacillus. There were thirty-nine of these cultures, twenty-three from adults and sixteen from children. Of the calves experimented upon with the cultures from adult subjects, nineteen presented no symptoms, nine presented very slight local changes at the end of four months, and seven showed more distinct evidences of infection, but there was no generalized tuberculosis. Of the calves inoculated with cultures from tuberculous children four presented mild symptoms of bovine tuberculosis and two died from the fully developed disease. In view of these results it is difficult to understand how the commission could arrive at the conclusion that "the series of experiments strengthens Professor Koch's view that animal consumption as the cause of human consumption does not play the rôle generally attributed to it, but definite judgment requires further experimentation." This was certainly not the deduction made by Professor Orth, Virchow's successor, who in the discussion on the report strongly combated the view that human and animal consumption were dissimilar and non-transferable.

**The Chicago Eye, Ear, Nose, and Throat College** has recently introduced a house-service in its hospital. As the result of a competitive examination Dr. H. E. Goldberger was appointed house surgeon to serve for a period of eighteen months.

**The Drexel Institute of Art, Science, and Industry,** of Philadelphia, has recently instituted a new department of instruction, viz., a preparatory course for nurses to extend over two terms. Instruction is given in the elementary medical branches, anatomy, physiology, etc., as well as in cooking, gymnastics, voice culture, facial expression, English, etc. To those who complete the two courses satisfactorily a certificate of attendance will be given. For the first year a first and second prize of thirty and twenty dollars repectively is offered by Dr. S. Weir Mitchell for excellence in all the branches.

**The City Sanatorium for Consumptives.**—The New York City Board of Estimate and Apportionment will soon, it is understood, be requested by the Mayor to grant the sum of $500,000 for the purchase of a site and the erection of suitable buildings for a sanatorium for cases of incipient tuberculosis. This project has been under consideration for a long time, but action on it has been delayed by other, to the lay political mind, more important considerations. There are now in this city it is estimated, 30,000 incipient cases of tuberculosis, the greater number of them being in the thickly populated tenement-house districts. Until recently the city authorities have had practically no equipment with which to meet this menace. Now, however,

there is a temporary hospital for such cases on North Brother Island, and some tents have been put up recently on Blackwell's Island, to form an adjunct to the main institution. Only a few cases, however, can be cared for at these places, and the need of a larger sanatorium is believed to be imperative. It is proposed to purchase a site of some 500 acres, probably in Orange or Rockland county, New York, on the highlands west of the Hudson River. When the work begins, foundations for an institution of great proportions will be laid, and the number of buildings erected at first will be added to from time to time by means of additional appropriations.

**The Jersey City Free Dispensaries.**—The free dispensaries in Jersey City were reopened for the summer last week. They are located in drug stores, and at each is stationed a physician, who remains on duty from 5 to 6 P.M. and from 8 to 9 P.M. each day. The appropriation to run the dispensaries is made by the Board of Finance. All worthy persons without means, and especially mothers with ailing children, will receive free medical advice and the necessary remedies.

**Dengue in Hawaii.**—Dengue is reported epidemic in Honolulu and other parts of the Hawaiian Islands. In Hilo the court was adjourned for a week at the end of June because of the illness of so many jurors, lawyers, and court officers. The mosquito is believed to be the active agent in the transmission of the disease.

**Fourth-of-July Casualties.**—Each year, after the smoke of the conflict has lifted, the *Chicago Tribune* collects the statistics of the killed and wounded in the name of liberty. This year the number of deaths in 210 towns was 52. The number of injured was 3,665, 1,376 from fireworks, 319 from cannons, 1,121 from firearms, of which 559 were from the so-called toy pistol, 768 from the premature explosion of gunpowder, and 81 in runaway accidents caused by the noise. No account is taken in these statistics of the cases of tetanus following the Fourth-of-July wounds, reports of which are now coming in. The fire losses amounted to $400,625, and all this in only 200 towns!

**Mosquitos.**—For two summers much has been said and sung of the labors of the mosquito exterminating committees of the various residential suburbs of New York, especially of those in New Jersey, and the optimists looked forward to the time when the insect would be heard no more. But, alas for science, this summer is witnessing one of the most remarkable plagues of mosquitos experienced in years, and the pests are more numerous and more vicious than ever before in the memory of the oldest commuter. All the near New Jersey towns report unusual numbers of mosquitos, and on Long Island the villages along the bays and adjacent to the meadows are especially effected by the mosquito plague. The pest is not the ordinary *Culex pipiens* with her gentle crescendo diminuendo hum and irritating, indeed, but not venomous sting, but the roaring, plunging *C. pungens* with a voice like the exhaust of a locomotive, and a proboscis tipped with oil of vitriol. There is still another variety which is said to be dumb, having no song to disturb the stillness of the evening, but with venom enough in her sting to atone for any vocal defects. The cause of the plague is believed to reside in the meteorological conditions prevailing during June, when the incessant rains and absence of sunlight created numbers of temporary ponds free from fish, and admirably adapted to serve as breeding places for the mosquito. The faith in kerosene being thus shattered, the victims are reading with hope of an intestinal parasite which is said to be deadly to the mosquito. According to the reports, a round or hair worm of the family of *Mermithidæ* has been discovered, which, in its larval state, is parasitic, being found in the bodies of mosquitos. The infested insects are sluggish in their movements, do not oviposit, and soon die. A long drought followed by heavy rains result in the worms leaving the bodies of the insects and returning to the earth. Dr. Charles Wardell Stiles has given the name *Agamomermis culicis* to this species of *Gordius*, and it is hoped that some means may be discovered of favoring their increase until there will be larvæ enough to provide every lady mosquito with at least one.

**Tuberculosis Committee of the Charity Organization Society.**—Some time ago this society made an appeal for money to meet the expense of opening a home in the country for young women in the incipient stages of pulmonary tuberculosis. Two thousand dollars have been received, and board in private families for a limited number of patients has been provided. For $5,000, however, a suitable house could be rented and equipped, and an average of twenty patients cared for during the year, and the society makes another appeal for this amount.

**To Determine the Noxious Effects of Tobacco.**—The experiments which have been conducted for several months past in Washington to determine the effect upon the organism of various foods preservatives have been concluded, and the results will, it is stated, soon be made public. Dr. Wiley of the Agricultural Department now announces his intentions of making a new series of experiments to determine the effects of tobacco, smoked, chewed, and possibly snuffed, upon the respiratory, circulatory, digestive, and nervous systems Men who are regular smokers will be examined, their physical condition as to heart action, breathing, digestion, etc., while continuing the use of tobacco under normal conditions being carefully noted. Then they will suddenly cease the use of tobacco entirely, After the effects of the prolonged use of tobacco have been eradicated from the system, it is proposed that the subjects of experiment shall recommence the use of tobacco, beginning in small quantities, which will be gradually increased until they are using as much as when the experiment first began, or more. The difficulty in these experiments will be to persuade the men to abandon the use of tobacco, or to be sure that they are not smoking or chewing surreptitiously while apparently abstaining.

**Home for Convalescent Patients.**—The Lebanon Hospital, situated in the Borough of the Bronx, is working to secure a fund to establish a building for convalescent patients. The United Hebrew Charities of New York has recently donated to the hospital $5,000 toward this fund. This institution is not for any particular nationality or creed, but receives patients of every class irrespective of such conditions.

**Dr. R. M. Pearce** of Philadelphia has been appointed adjunct professor of pathology and bacteriology in the faculty of the Albany Medical College, and director of the Bender Hygienic Laboratory. He will succeed Dr. George Blumer who retires on September 1. Drs. E. McD. Stanton of New York and C. K. Winne of Mount Wilson, Md., will be his assistants.

**Straus Milk Depots in Other Cities.**—Mr. Nathan Straus has been requested by the Health Commissioner of St. Louis to establish sterilized milk

stations in that city similar to those so long in operation in New York. He has promised to see that stations are established there next summer, but on account of the time required to secure the machinery for the pasteurizing plants it will be impossible for a system to be completed in St. Louis this year. He has just donated a pasteurization plant to the Children's Hospital Society of Chicago.

**Obituary Notes.**—Dr. SAMUEL J. RADCLIFFE, one of the oldest practising physicians in the District of Columbia, member of the Medical Association of Washington and a veteran of the Civil War, in which he served as medical director, died at his home in that city on July 9 in the seventy-fifth year of his age. Dr. Radcliffe was born in Washington and was graduated from Georgetown University in 1852 and almost immediately entered the army as assistant surgeon. He rose to be medical director with the rank of lieutenant colonel. He was mustered out on October 7, 1865. He was again appointed assistant surgeon in the army in 1866 and served until 1884.

Dr. F. J. B. ROHMER, one of the best known retired physicians of the South, died at Mobile June 30, aged ninety-one years. He was born in Alsace. He was a graduate of the Medical Department of Tulane University, New Orleans, in 1836, and was one of the founders of the Charity Hospital in New Orleans.

Dr. CHARLES E. NASH of Little Rock, Ark., died on July 8. He was born in St. Louis and was a graduate of the Missouri Medical College in the class of 1849.

Dr. CHARLES LANCASTER died July 6 in Plainfield, N. J., at the age of ninety-five years. He was both a lawyer and a physician and practised as the latter many years. He was also a talented writer, and in early life was intimately acquainted with Emerson and Longfellow. He formerly lived in Philadelphia, but removed to Plainfield about eight years ago after retiring from practice.

Dr. G. DALTON HAYS died at his home in Tenafly, N. J., on July 3. He was graduated from the College of Pharmacy in this city in 1878, taking the gold medal, and served as instructor in the college for many years. He was also graduated at the College of Physicians and Surgeons, New York, in 1884, and became a member of the Academy of Medicine, and was secretary of one of its sections. He was also a lecturer at the Post-Graduate Medical School and at the Training School for Nurses. He was a son of David Hays, who was vice-president and treasurer of the College of Pharmacy for many years.

---

**A Study of Korsakoff's Disease.**—Serge Soukhanoff and Andre Boutenko report a number of cases of polyneuritic psychosis or Korsakoff's disease. Altogether there are 192 cases on record, 112 in men and 80 in women. Chronic alcoholism is the chief cause of the disease, typhoid fever comes next, then follow pyæmia and jaundice. Korsakoff considered the disease to be an individual one, accompanied by a peculiar and constant psychic condition, the main feature of which was amnesia. The most characteristic trait of this mental impairment consisted of pseudo-reminiscences. The authors give the history of the literature of the subject and the results of their own investigations. They have found that death is a frequent termination of the disease, and tuberculosis is often the immediate cause. Cases of complete recovery are rather rare. In half the cases in men psychic defects are left. Encephalitic processes with softening of the hemispheres is seldom the cause of death in polyneuritic psychosis.—*The Journal of Mental Pathology.*

## OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENTARY; SANITATION; VIVISECTION—HONORARY LONDON DEGREES—CANCER—THE CARLYLE CONTROVERSY—ACLAND'S BIOGRAPHY—BIRTHDAY HONORS—GIFTS AND BEQUESTS—DEATH OF A WOMAN DOCTOR FROM A POST-MORTEM WOUND.

LONDON, June 26, 1903.

THE House of Commons yesterday talked over many subjects which could be introduced on the vote for the home office. Among them lead-poisoning in pottery work, ventilation of weavers' sheds, sanitation of laundries, women inspectors, vivisection. As to the sanitary questions in the above list, surprise and even vexation was expressed at the distrust of the local authorities manifested in some quarters. The Home Secretary made a very good defence of his department. The steady decline in lead-poisoning cases was satisfactory, but further precautions were being adopted. In respect to small laundries, voluntary inspectors had been most useful and had proved to those interested that inspection was not to be feared. Strong objections were expressed to any rules which would crush out the poor women engaged in this trade and give it over to large factories.

Sir M. Foster spoke on vivisection and protested against the violent terms that had been applied by its opponents. He resented such expressions as "torture dens" and such adjectives as "fiendish," "hellish," etc., and then he instructed the House as to what vivisection really had accomplished, and as to what experiments were really carried on.

Dr. Hutchinson also repudiated the epithets which had been applied to the profession, and declared it would be shameful for them to pass unchallenged in that House. When a member or his wife fell ill, the first man sent for would be one who had gained his knowledge from the results of experiments so unjustly vilified.

The University of London has made a further approach to the customs of the older universities by conferring, for the first time in its history, honorary degrees.

The Prince of Wales was made Doctor of Laws, the Princess Doctor of Music. Lord Kelvin and Lord Lister, Doctors of Science.

The Earl of Roseberry, as Chancellor, said he hoped that this would not be an annual celebration, but that in future only those worthy to stand on the same plane as the new doctors would be given honorary degrees.

The directions and avenues through which cancer may possibly be more successfully treated formed the subject of a paper at the Gynæcological Society by the veteran Dr. C. H. F. Routh. He enumerated certain points which he considered have been made out and supported his conclusions by references to other observers. It is hereditary, contagious to the patient himself, has been inoculated in animals, favors certain localities and even houses: statistics point to the neighborhood of forests and to trees round the houses, as well as to two beverages—beer and cider. Such are some of the points Dr. Routh put forward as settled. Then he passed on to note the increase in the disease, its uneven "patchy" distribution and relation of houses to soil. The curious way in which cancers have disappeared after exploratory operations was then considered and the influence of exposure to the air suggested as the cause—oxygen being the agent. Plants do not flourish on all soils nor in all climates, nor even in all seasons. Animals exposed to unsuitable changes soon die. So may not microbes perish when their modes of life are entirely changed? Dr. Routh referred to the generation of a cancer parasite as one that we could not speak of as proved. Still he seemed to attach great importance to microorganisms, and his recommendations for treatment were directed toward their destruction. Thus he advises the employment of oxygen freely to render the injurious effects of organisms inoperative, and pointed out the need of further experiments on their destruction by means of electrical shock or vibrations or by freezing with liquid air and crushing, as in Dr. McFadyen's treatment of typhoid bacilli.

Further, Dr. Routh urged a perfect system of drainage and water supply, flushing of drains with electrolysed sea-water, and the use of this water for watering the streets, combating fires and providing baths—a plan he has previously advocated in a pamphlet on "Water Supply in London."

Two remarkable cases were related by Dr. Routh, in which apparently malignant disease disappeared under the use of sol. peroxide of hydrogen.

In the discussion that followed, Dr Herbert Snow objected to the use of the word cancer in almost all investigations in a vague way, as the name of a single

disease. The first thing toward getting a clue is to differentiate malignant diseases. From statistics he formerly gave he showed cancer was no more hereditary than toothache. He did not know one well-authenticated case of communication to others. In so-called cancer-houses the cases were of different varieties. The parasite theory could not explain the duplication of the original tissue involved in other structures, *e. g.* mammary tissues in the liver, etc. He did not find hydrogen peroxide superior to iodine.

Dr. B. Fenwick had not found one case communicated, and very few with any ground for supposing them to have been heredity.

Mr. Skene Keith believed in heredity. He had met with cases of disappearance after incomplete operation.

Dr. Mansell Moullin did not class papilloma as malignant. He once had to open the abdomen four years after removing papillomatous ovaries, and found no trace of the disease.

Dr. Heywood Smith mentioned a case operated on thirty years ago, and from which he felt sure the disease was communicated to another woman, operated on four days later.

Dr. Routh, in his reply, thought the evidence of heredity strong, when four or five generations of one family were affected. As to "cancer-houses" he was convinced by the careful researches of men of ability and character. He felt certain that hydrogen peroxide was too much neglected, and remarked that an eminent Russian professor had reported the cure of six out of seven cases.

The fresh outbreak of the Carlyle controversy has become more acute since I wrote to you about it. It is also receiving more attention from the profession, for although every one has some pretension to interest in literary matters, more medical points have been raised. The general journals seem to be taking just the line they had taken in the earlier discussions, thus illustrating a partisanship which they cultivate in politics. Sir J. Crichton-Browne's attack on Froude—he calls his statements "Froudacities"—naturally roused the friends of that writer, who have, accordingly, published a manuscript he left entitled "My Relations with Carlyle." Those two publications are occupying the press, and their statements will be sifted over and over again. From the purely medical aspect there is something to be said, but less, I think, than is so generally assumed.

The *British Medical Journal* on Saturday gave a pretty full account of Dr. Gould's views without, however, endorsing the diagnosis of eye-strain as the origin of Carlyle's sufferings. But the suggestion is being discussed freely and the *Journal's* articles is making Dr. Gould's book more known. From Froude's "My Relations with Carlyle" the *Medical Press* of Wednesday extracts quite another interpretation in an article entitled "Genius and Impotence." Quoting the statement that "Their marriage was not a real marriage, and was only a companionship," and that "Carlyle was one of those men who ought never to have married." The *Medical Press* finds that these and other statements need no explanation for medical minds. Of course, Sir J. Crichton-Browne is shocked and assails Froude with a choice selection of vituperative expressions. But what has the public or the profession to do with such disputes? Why not let the matter rest?

Of literary contributors to the controversy I sympathize most with the view of Mr. Andrew Lang, who, in his turn, sympathizes with Tennyson's irony, and in reply to the assertion that the world has a right to know everything about its great men, holds, on the contrary, that the public has no more right to pry into the "secrets of a great man's life, than to stare into a small man's windows, or to open his dispatch box."

He observes that there are some people who would rejoice to find and publish a diary and correspondence of Mrs. Shakespeare, and arouse a controversy in which one party would declare Shakespeare was a brute, and the other that his wife was a shrew. Happily, Shakespeare's heart cannot thus be "torn before the crowd." So in a playful manner he enforces this view by suggestions in case a diary of Xanthippe were at hand. It might be found, he says, that Mrs. Socrates declared her husband never talked metaphysics with her after the honeymoon, and as to his so-called Dæmon, she implored him to consult Dr. Hippocrates about it, for she believed that the Dæmon was only liver, if not brain trouble. But he never would."

The late Sir Henry Acland, F.R.S., held so prominent a position for so long a period at the University of Oxford that his biography has been looked for as a treat by Oxford men. It will interest others too, for the energetic Regius Professor of Medicine was brought into contact with most of the leading lights in literature and politics as well as science. The memoir by Mr. J. B. Atlay is rather a bulky volume, and the letters included almost too numerous, but the work as a whole is one to afford much pleasant reading. Acland's life aim was to bring the scientific work of the University, which was almost extinct, up to a satisfactory state, and this he accomplished after years of desperate opposition on every side. He found the intellect of the University wholly given to ecclesiastical and theological questions, when Pusey could talk of "the evils and dangers of scientific study." He left a school of science of which the University need not be ashamed, he saw no opposition between religion and science, but was himself a deeply religious man of artistic and intellectual tastes.

The King's birthday is officially celebrated to-day in London and all home stations. A long list of honors is announced this morning as conferred in celebration of the occasion. Four medical knighthoods are included. Stephen Makenzie, Patrick Heron Watson (Honorary Surgeon to His Majesty in Scotland), A. D. Fripp, C.V.O., and E. C. Perry. The two last named in recognition of their services on the Army Medical Advisory Board.

Lord Iveagh has offered £34,000 to build science laboratories at Trinity College, Dublin, on condition that the necessary annual outlay is provided for within three years from next May.

The widow of Sir T. D. Brodie, first baronet, has left a sum of money to charities (subject to a life interest) which it is expected will eventually be about £120,000.

Miss Bryson, M.B., Lond., Assistant Medical Officer, Camberwell Infirmary, died on the 15th ult., from septic poisoning, the result of a wound in the finger made when performing a post-mortem examination. She took her degree in 1900.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

SANITARY AFFAIRS IN MANILA—RESULTS OF THE TROZO FIRE—THE CHINESE PLAGUE HOSPITAL—GIFT OF LAND FOR THE NEW GENERAL HOSPITAL—A PROPOSED NEW HOTEL IN MANILA—EXHIBIT FOR THE ST. LOUIS FAIR—OPPOSITION TO THE OPIUM CONCESSION—DESTRUCTION OF LOCUSTS BY THE GRASSHOPPER FUNGUS—THE MANILA MEDICAL SOCIETY.

MANILA, June 1, 1903.

THE sanitary conditions in Manila have lately been quite seriously influenced by the recent fire in the Trozo native district of the city, which destroyed some 3,000 houses and rendered more than 15,000 people homeless. Many of these people have crowded for shelter into other native districts, already far too much congested, while others are camped under makeshift shelters on the sites of their former homes. Under the latter condition particularly, it is hard to maintain proper sanitary conditions and soil contamination is inevitable, as is the case in large military camps. The health authorities are now engaged in providing temporary latrines and other conveniences, and are also planning to take advantage of the wholesale house destruction caused by the fire to ensure that the new buildings to be erected shall comply in their arrangement and construction with sanitary requirements. This task is much easier through the fact that the ground of the entire devastated area belongs to the San Lazaro Hospital administrators, and the individual lessees can thus be brought more directly under the city authorities. Among other things, it is proposed to widen the roads in the district, reduce the size of the blocks, permit the erection of no house which does not front on a street, and establish a common latrine in the center of each block, where it can be cared for by the employees of the "pail system." Sanitation, cleanliness, and removal of excreta can thus be more effectually secured, and the danger of such widespread destruction from future conflagrations will be materially lessened. As things have been in the past, the existence of these closely built native districts of inflammable nipa houses has meant a constant menace to the safety of the city. Had the wind been blowing from another direction on the day of the Trozo fire a much larger part of the city would have been fire swept, as whole blocks of houses flashed into flame from sparks carried more than a quarter of a mile by the high wind. The great deficiency of the water supply of Manila was seriously felt on the occasion of the Trozo fire, as sufficient water could not be secured to make any appreciable effect on the flames.

After the fire the authorities issued free rations to those who needed them, and the Board of Health pitched some five hundred tents for their shelter. The latter were not appreciated, however, as the natives largely preferred to live under flimsy shelters of matting, iron roofing, and similar material. Personal feeling seems also to have entered into the matter; as the Board of Health has been condemning and burning a considerable number of plague houses lately, and it appears that the insurrecto

element has largely spread the story that the Trozo fire was started and spread by the Americans, and particularly by those connected with the work of sanitation. This story appears to be more or less generally believed by the ignorant class of natives, who seem to place more credence in a story the more extravagant it is. For this reason the efforts of the authorities to shelter the homeless seem to have been largely unavailing.

The Board of Health itself lost much property by the Trozo fire, and the losses in the corral of the "pail system" for the disposal of excreta will alone amount to some $50,000. Except a few horses and ambulances, nothing was saved from the plant of the "pail system," and the transporation corral of the Board of Health. The flames also leaped the high stone wall of the San Lazaro Hospital grounds and completely destroyed the buildings of the cholera hospital, and those of the large detention camp for contacts and suspects with plague, cholera, and smallpox. These buildings had a capacity of some 1,500 people, but, fortunately, at the time of the fire there were only a few occupants. None of these lost their lives, but the flames spread so quickly that all property was a total loss. The flames extended so rapidly that it looked for some time as if San Lazaro Hospital itself would get on fire, and the lepers and venereal cases were removed to a place of safety. Much credit is due to Dr. Wilkinson, the superintendent of the hospital, for his excellent work, but for which much more property must have been lost than was actually destroyed. As it was, it looked as if the Board of Health work would be seriously crippled by the fire, but energetic work soon brought matters into working condition, and inside of twelve hours the machinery was running as smoothly as if nothing had happened. Tents were pitched and the cholera hospital established therein, new transportation was secured for the ambulance service, a new office was opened for the "pail system" and its outfit renewed from the storehouse. The local press has been loud in the praise of the health authorities for the way in which they handled the situation.

As a result of the fire, work on the new contagious disease hospitals, already planned for, is being expedited, and ground has already been broken on the site of the old cholera hospital and detention camp for their construction. The plan calls for an administration building with pavilion wards for the patients. There will be two wards for smallpox, one each for male and female cases, two for plague and four for cholera. These buildings will be thoroughly modern in their equipment and well built according to plans similar to that of the Chinese plague hospital.

The Chinese plague hospital, built by the Chinese merchants, has, fortunately, just been completed, and forms one part of the proposed contagious disease hospital for the treatment of plague, cholera, and smallpox. Other wards for the two latter diseases, with a convalescent ward, are shortly to be erected. A reception ward is now being built and storerooms and quarters for the attendants will be provided later. The whole plant is to have its own water supply from a driven well, and when complete will be thoroughly modern and well equipped. The hospital buildings are raised well above the ground, which is cemented. They are built on the pavilion plan, are of hard wood with corrugated iron roofs, have impermeable walls and floors, wide porches, shell windows, and very free ventilation. This style of architecture is not expensive, seems to be most suited to the Manila climate and conditions, and is very sanitary, cool, and comfortable. At one end of each ward is a semi-detached kitchen, and at the other end a similar annex containing baths, water-closets, and storerooms. Each section forms a complete isolation hospital for its own disease, and all come under a single management. As fast as the sections are built, the old insanitary buildings which have heretofore been used for the Chinese having contagious diseases will be burned. The site of this new isolation hospital is better than that of any other hospital in Manila, except that it is a little too far to be as readily accessible as could be desired.

The much-vexed question of a site for the new general hospital has finally been settled, after a site had been decided upon, by the presentation by Senor Legarda, one of the Filipino members of the commission, of about twenty-five acres of land in the Sampaloc district. The only conditions attached are that the hospital shall be called after Governor Taft, and that Filipino physicians and their patients shall have certain rights; though this latter point is not insisted upon, and is left to the judgment of Governor Taft and Bishop Brent, representing the hospital committee. The new hospital site is well drained, and while well away from the turmoil of the city, is sufficiently close for convenience. Senor Legarda is a very wealthy man, and has been much impressed with the splendid charity of the movement to erect the new hospital. The work of collecting funds and preparing plans is going on rapidly, and construction will be begun at no distant date.

The old unfinished Cosmopolitan Hospital building has been sold to the city government of Manila, to be completed and used as an office building. After its sale, a syndicate made an offer to the city for the property, in excess of purchase price, for use as a hotel which is to be provided with all modern conveniences and service. The hotel company also desires a lease of a certain amount of adjoining government land which is at present unoccupied, and which it proposes to convert into a small park in connection with the hotel. As there is much need of such a hotel in Manila, and as the proposed offices of the city government can be located much more conveniently elsewhere, the proposition of the hotel people is being favorably considered and will probably be approved. All this has a bearing on the welfare of the general hospital, as it is understood that the funds to be acquired by the sale of the Cosmopolitan Hospital are to be turned over to the new hospital. This fact largely influenced the Manila government officials in their decision to purchase the property for official purposes, as the need of a large properly equipped general hospital is seriously felt.

Pending the construction of the new general hospital, the members of the Hospital Committee, of which Bishop Brent is chairman, are casting about for some building suitable for temporary use to meet present needs, which are very urgent. The committee is desirous of securing the old military Third Reserve Hospital, which is now used as barracks for infantry and a company of the Hospital Corps, and has taken up the matter with the military authorities. It is expected that the commission will make formal application for the buildings, and it is believed that the consent of the Secretary of War can be secured for their transfer. With but few repairs and changes the buildings can be put in a condition to excellently fill the purpose for which they are wanted; they are centrally located and can probably be given up by the army without serious inconvenience to the service.

The Civil Hospital, an institution of one hundred beds, operated by the Civil Government for the benefit of its employees, has been placed under the control of Major Carter, the Commissioner of Health. Dr. Frank DuBois has been placed in charge during the absence of the attending physician and surgeon, Dr. E. G. Stafford, who has gone to the Benguet Sanitarium to recover from an attack of malarial fever. Dr. Stafford was lately placed in control of the hospital with the title of Chief Surgeon. Dr. Charles Fitzpatrick, who has formerly been attending physician and surgeon at the Civil Hospital, is to become police surgeon, and the work of resident and assistant physicians is to be performed by two physicians selected from the civil-service appointees.

A very complete exhibit for display at the St. Louis Exposition is being prepared by the health authorities of Manila. A committee has been appointed to take charge of the matter, has been granted a thousand dollars to meet the necessary expenses, and has been allotted four hundred feet of display space for the exhibit. The latter will include specimens of all publications, reports, circulars, forms, and other printed matter issued by the Board of Health. There is to be an elaborate series of maps and charts having to do with the distribution and prevalence of some of the more important diseases met with here. Perhaps the most striking feature of the exhibit will be a large series of photographs covering every phase of the work of the Board of Health, the obstacles to be overcome, the conditions as they existed prior to American control, and the sanitary improvements which have been made up to the present time. There will be a particularly complete series of photographs illustrating the work being done against plague, cholera, and leprosy; and the prevention of the animal diseases prevalent in the Philippines will be given special importance. The Board of Health expects to make an exhibit which will be both interesting and instructive, and show what the Americans have been able to accomplish in a sanitary way during the occupation of the islands.

Strong opposition to the proposed granting of an exclusive concession for the importation and sale of opium has developed in several quarters. The Chinese are fighting the proposition because it will create a monopoly which will unduly raise the price of opium and bring opium smoking into the class of luxuries; while the Evangelical Union and other reform bodies are fighting it because they think that the Chinese should not have opium at all, and that its importation, except as a medicine, should be prohibited. The case is much similar to the fight against the army canteen, in which the W. C. T. U. and the saloon-keepers united their forces to destroy that institution.

The Evangelical Union, in its memorial, states its belief that the admission of opium constitutes a grave economic peril; and that the opium habit at present destroys the health and efficiency of as many citizens of these islands as leprosy itself. It states that the use of the drug is rapidly spreading among the Chinese and the lower class of Filipinos, and that one in five of the Chinese, in the islands, are victims of the opium habit.

The Chinese, on the contrary, have issued a statement to the effect that the use of opium is as much of a necessity to Chinese as the use of food; that while nearly all Chinese smoke opium to a greater or less extent, not 2 per cent. of those in the islands are slaves to the drug; and that the granting of the proposed concession would put the price of opium so high as to be beyond the reach of the poorer Chinese. For these reasons they desire that the concession be not granted. It is a case of two diametrically opposing interests being united on a common proposition.

The destruction of locusts is being carried on in the provinces with much success by the sanitary authorities, though the late dry weather has somewhat interfered with the work. The grasshopper fungus, so successfully employed in the Western States in the destruction of grasshoppers, is used here in fighting the locust plague. The fungus is placed on small pieces of bread, which are strewed in the path of the locust swarm and upon which they greedily feed; or locusts are caught, infected with the fungus, and thrown back into the swarm. The fungus acts quickly and certainly, and within twenty-four hours the locusts die by myriads, as many as a hundred bushels having been collected from the dead locusts of a single swarm. Once a swarm is located, those in charge of the work of destruction follow the swarm for days until practically all the locusts have been destroyed. As a certain amount of dampness is necessary to the development of the fungus, much of the work during the dry season is done at night, when the heavy dew is of much assistance. There has been some little opposition by the natives to the destruction of the locusts, which they regard as a valuable food, and this opposition has been particularly excited as the locusts which have died of fungus disease are unfit for food and cause grave intestinal disorders. This is the case to such extent that the health authorities have found it necessary to send word to the provinces where the locusts are being destroyed, prohibiting their use as food by the natives. As the locusts lay their eggs in the ground, it is thought that the plowing up of the eggs by more general cultivation of the fields, and the destruction of the adult insects by fungus, may ultimately cause the extermination of the locusts in the islands.

The Manila Medical Society is considering the advisability of establishing a medical journal, and has lately held several meetings to discuss the matter. There seems to be some opposition to the project. The native physicians cannot be counted upon to support such a publication in any way, and it is difficult to see how, with the very limited circulation such a paper would necessarily have, the venture could result in anything but financial failure. The small size of the society is also such as to scarcely ensure sufficient contributions to fill the columns of the proposed paper.

One defect of the Manila Medical Society would seem to be the fact that it is administered too much as a civilian organization, and but slight effort is made to interest the medical men of the Army, Navy, Marine Hospital, and Civil Service in and around Manila in its work. The latter class certainly outnumbers the English-speaking physicians engaged in civil practice here, and contains some of the most able men in Manila. The society can never prove of the maximum benefit until it breaks away from its present restricted policy and seeks the support of the government physicians here, who can add much to its strength, dignity, and importance in the medical world. There is no reason why a society conducted on broader lines should not prove to be of the greatest value, particularly in respect to the investigation and study of tropical diseases.

---

**Heat Exhaustion.**—William F. Waugh says that the victims of heat exhaustion are most frequently fat, middle-aged men—victims of the ice-water habit. Free perspiration ensues, the sweat carrying with it the salts of the blood; dyspnœa occurs and the patient faints. If he is bled, ice applied to the head, and the classic treatment of sunstroke given, he quickly succumbs. The readiest treatment is by glonoin, gr. $\frac{1}{150}$ to $\frac{1}{100}$, dissolved in a few drops of water and put into the mouth, quickly absorbed by the buccal mucosa. Atropine, gr. $\frac{1}{150}$ to $\frac{1}{100}$, should be given simultaneously. The patient's head should be kept low. The general and profound vasomotor paresis is combated by brucine, of which a milligram, gr. $\frac{1}{65}$, may be given every half-hour till the desired degree of vascular tonicity has been secured.—*Virginia Medical Semi-Monthly.*

*The Boston Medical and Surgical Journal, July 9, 1903.*

**A Case of Acute Epididymitis in an Undescended Testicle, with Gonococci Demonstrated in the Excised Organ.**—Fred T. Murphy reports this case. The patient was a man twenty years old. The left testicle had never been in the scrotum, and five weeks before he had contracted his first gonorrhœa. There was a small lump in the left groin, very tender and painful. In both groins the glands were slightly enlarged. On the left side just above Poupart's ligament, and external to the external ring, was a tender tumor, apparently distinct from the glands. The external inguinal ring was plugged with a mass which seemed to extend on the external oblique fascia to the tumor. Diagnosis was made of acute inflammation of an undescended testicle. At operation the indurated cord was tied off as high as possible with catgut, and the fascia caught together with interrupted stitches of the same material, a small drain being left in the inguinal canal. The patient left the hospital on the eighteenth day. It was a case of epididymitis without abscess formation, the usual clinical condition. Microscopical examination of the pus showed diplococci like gonococci. The gonococcus clearly was the infecting agent in this case. The writer believes that it is the microorganism concerned in all cases of epididymitis with gonorrhœal urethritis, possibly rarely associated with a mixed infection. The evidence is, that this affection is not due to the absorption of toxin from the urethra or to the primary infection of other microorganisms. Clinically, the differentiation from the other possibilities of acute inflammation, as adenitis, incarcerated or partly strangulated hernia, is not without interest.

*Journal of the American Medical Association, July 11, 1903.*

**Continued Fever, Neither Malarial nor Typhoid.**—T. J. Happel claims the existence of a "third" fever which does not respond to the Widal test and does not show the organisms of malaria in the blood. He advances the rather novel theory that when a blood smear is sent to the laboratory the history of the case should be purposely omitted so as not to influence the pathologist. He then describes several cases of this "third" fever, and points out what he considers its clinical peculiarities, but, on looking over the histories of his cases, we discover no greater departures from the normal typhoid and malarial types of fever than we are accustomed to see in Northern cities at least in cases that belong unmistakably to one or other of these categories. As to the negative results of bacteriological and microscopical examination, we have no explanation to make. Possibly persistence in the application of laboratory methods may result in evidence altogether different.

**The Management of Fever in General.**—A. A. Eshner states that fever is most commonly due to changes secondary to infective processes—that is, to the toxic effects of the products of bacterial and cellular aotivity. The regulation center governing the amount of heat production lies in the central nervous system. While there may be a theoretical difference between fever and pyrexia, there is no practical difference—at least, none from the clinical standpoint. It has been thought that elevation of temperature in the presence of infectious diseases is a conservative process, perhaps having antibacterial or antitoxic value, but as to the accuracy of such a view the evidence is not conclusive. The great problems that confront the clinician are to remove the cause of the fever in so far as it is possible and to restore metabolic equilibrium. It may be impossible to do much along the line first mentioned, but we have at our disposal emesis, catharsis, diaphoresis, diuresis, enteroclysis, hypodermoclysis, and intravenous transfusion. Acting along the second line we may employ various baths and sustain the heart and lungs with the usual stimulants. Antipyretic drugs are not necessary as a rule, and their use is at all times attended with danger.

**Southern Fevers.**—W. Krauss discusses the question of fever occurring in the Southern States with special reference to the possibility of an "*x*" fever, neither malarial nor typhoid. His conclusions are as follows: (1) A very sudden hyperpyrexia in midsummer is more apt to be sunstroke than "congestion." Do not give quinine without cause. (2) The malarial leucocyte count is only collateral evidence of malarial infection, and the count must include all the cells in the spread. (3) The Widal test may lead us into error in a small percentage of cases; the blood culture test is more difficult and has no negative value. (4) A chill or fulminant onset of a typhoid fever is not sufficient evidence of a complicating malaria. (5) A chill or sudden disturbance of the temperature curve during convalescence in typhoid fever is not necessarily malarial. (6) In a malarial infection the persistence of

an irregular subcontinuous fever after thorough cinchonization is not evidence of a typhoid complication or of remaining plasmodia. (7) A positive diagnosis of summer-fall fevers is not always possible. (8) In the hygienic management of summer-fall fevers we should presuppose a double infection, irrespective of symptoms. (9) Some of the summer-fall fevers are typhoid, some are malarial, and a few of them are neither one, but the writer is opposed to the belief in an *x* fever.

**A Clinical Observation of Ninety Cases of Typhoid Fever.**—These are analyzed in tabulated form by R. M. Harbin, whose conclusions are summarized as follows: (1) Fasting and a restricted diet are indicated because of pathologic conditions. (2) A clinical fact maintains that emaciation occurs independently of the amount of food taken. (3) All severe cases should be subjected to fasting for twenty-four to forty-eight hours to relieve the active symptoms, which exhaust the patient more rapidly than the lack of food. (4) After a fast should be prescribed a restricted diet of broths, diluted milk, etc., in definite quantities. (5) Gelatin prevents too rapid amaciation in certain cases and renders hemorrhage less liable. (6) The cold bath or the modified cold bath is more effective during a fast. (7) Peristalsis favors the absorption of toxins, and cathartics should be used only to remove undigested food. (8) The presence of intestinal ulcers should be assumed to exist in every case, and the proper treatment is rest, which is better attained by fasting and a restricted diet, thus preventing hemorrhage and perforation. (9) The presence of diarrhœa and vomiting indicates the adoption of the fasting treatment. (10) Fasting and a restricted diet shorten the course of the disease and many cases run an abortive course after the amphibolic period. (11) Many of the vaunted cures from specific drugs are dietetic in fact. (12) Recrudescences are nearly always due to dietetic errors. (13) In the above report, 45 consecutive cases occurred without death. Of 87 whites, 2, or 2.2 per cent., died. Of colored, 2 died, and the low mortality of 4.4 per cent. of all cases was ascribed to the above treatment.

*Medical News, July* 11, 1903.

**Notes on the Selection of a Climate for the Treatment of Tuberculosis.**—Russell Bellamy emphasizes the following points: Consumptives with a rapid breaking down of lung tissue should avoid high altitudes. So also should those of neurotic temperaments. Those with especially developed cardiac lesions, with a marked tendency to a disturbance of cardiovascular balance, should avoid high altitudes. Those completing the fifth decade, where the capacity of muscular exertion is considerably limited, should avoid high altitudes, although the writer has heard of many cases being taken to Colorado, recovering and taking up their life there. Laryngeal cases do better at the low altitudes.

**Dry Superheated Air in the Treatment of Septic Infection.**—Clarence Edward Skinner declares that although dry hot air in the treatment of septic infection is a "good thing," still its results are not invariably successful. Individual idiosyncracy, or variations in the inherent malignancy of different instances of even the same types of infection often present themselves as powerful factors working against the satisfactory action of any curative agent. Dry hot air will, alone and unaided, cure many cases; others will require all the remedial sources at our command, while still others will resist our every effort. It is simply a rational curative measure exerting a known and constant physiological action, and which, either alone or in combination with other agents, greatly increases our power to overcome this condition in the majority of cases. The writer then cites several cases illustrative of the beneficial effects of this treatment. In cases in which streptococci have been found in the blood, and in puerperal sepsis, there is apparently no reason why there should not be beneficial results from this method of treatment. It affects physiological function in two ways: first, by a direct stimulation of cell metabolism in the part treated, due to the raising of its temperature *en masse;* and second, by a reflex acceleration of cell nutrition set up by the stimulating influence of the heat upon the numerous nerve endings in the skin. The copious perspiration relieves the general circulation of a certain proportion of the toxin which is impregnating the body fluids. To the influence upon the circulatory function of the part whereby stasis is relieved, is probably due to the powerful influence of dry hot-air treatments in relieving pain and swelling. The physiological action of the body treatment is predominantly reflex through the spinal sympathetic, the area of skin affected being so great that the capillary circulation is able to dissipate the heat before it penetrates deeply enough to any great extent, therein differing from the local application. In case of pus, it must be evacuated, but even then hot air will localize the inflammatory action closely to the abscess cavity, when a stroke of the knife will end the trouble once and forever.

*New York Medical Journal, July* 11, 1903.

**The Source of Typhoid Fever.**—C. F. Davidson reports a series of cases of interest as to the mode of infection. Two were caused by infected butter packed in tins washed with water from an infected well that was responsible for six cases among those drinking water from it. Commenting on the fact that vegetables and fruit are often supposed to be the carriers of contagion, he says that he sees no reason why they may not be, but in his own experience he has always been able to trace the source of the trouble back to an infected well.

**Radiotherapy in Enteritis and Colitis.**—Sinclair Tousey has used radiotherapy in cases in which there is a chronic pain with frequent mucous discharges, together with occasional passages of blood or false membrane, and which have proved refractory to intestinal antiseptics given either by the mouth or by enteroclysis. He describes in detail the method of giving the treatment, but has as yet no definite results to offer. His expectation of lasting benefit is based not so much on account of the well-known germicidal effect of the rays as on account of the stimulating and alternative effect following their application when combined with the high-tension discharge from a vacuum tube.

**Report of a Case of Pernicious Anæmia with marked Ptosis of the Abdominal Viscera.**—C. B. Gay gives a very complete report of a case, reviews the history of the disease in general, and adds a bibliography. His patient was a married woman aged twenty-six years, presenting the usual features of the disease. Examination of the abdomen led to the belief that in addition there was a pyonephrosis which perhaps was at the bottom of the blood condition. Accordingly, the abdomen was opened, and what had been supposed to be a pyonephrosis was found to be an elongated right lobe of the liver, with an enlarged and dislocated kidney. The patient died three days after the operation. The clinical diagnosis in the case was pernicious anæmia, associated with cystitis, and an ascending pyelitis. The autopsy showed a general prolapse of all the abdominal viscera. The lymph glands showed an increase in their stroma with hemorrhagic extravasation with leucocytes predominating and disintegration of many corpuscles. The retroperitoneal glands showed all the characteristics of true hæmolymph glands. This latter point is, in the view of the author, of the greatest importance as bearing on the etiology of the disease. This point has already been dwelt on by Warthin, and the case of Gay seems to bear out the former's views.

**Some Observations on Stacke's Operation.**—T. R. Pooley contrasts the Schwartze and Stacke operations. He enumerates the dangers of the latter, mentioning the possibility of wounding the facial nerve, dura, lateral sinus, and semicircular canals, and the possibility of entering the internal carotid artery and internal jugular vein with the curette. Moreover, a radical cure is by no means assured by one operation, the length of time required for healing is considerable, and finally there is a possibility of permanent impairment of hearing in patients who before operation could hear fairly well. As to the indications for operations, he makes the following statements: The objective indications may be grouped under two forms: any case of reinfection or of a rapid extension of a chronic otitic process, or whenever a grave complication is threatened; the indication is then for immediate operation. The indication is not immediate when the patient suffers little or no pain and there is no striking symptom in the mastoid, but even here the indication may be to operate if the osseous lesion is extensive. The subjective symptoms are persistent and recurrent pain in the ear or mastoid process, with persistent and fixed pain in the parietal or occipital region, increased by percussion, which frequently points to temporal or cerebellar abscess; vertigo, either permanent or intermittent attacks, which may be due to erosion of the external semicircular canals; well marked brain symptoms, such as headache, heaviness, pressure, torpor, loss of consciousness, etc.

*American Medicine, July* 11, 1903.

**Two Cases of Appendicitis, and Some Deductions Therefrom.**—E. R. Secord reports these cases, in which the symptoms were not severe, but in both of which he operated. Early perforation would undoubtedly have occurred in each case had not operation been performed. The writer makes a strong protest against the description of opium as "the abiding resource of the great mass of conscientious physicians," and also against the charge that those who believe in the operative treatment are more interested in their skill in abdominal surgery than in their patients' welfare. If morphia be used it will relieve pain and tenderness, remove rigidity, decrease pulse-rate, and lower temperature—in other words, cover up all the symptoms of value in diagnosing the exact condition present. But it will not prevent the perforation of a gangrenous

appendix, nor will it absorb the stinking and infective pus from a periappendicular abscess. If morphia had been used in the above cases the result would undoubtedly have been perforation of the appendix.

**A Case of Double Curvature of the Spine with an Interesting Complication.**—Edward Judson Wynkoop reports this unusual case. The patient was a boy of three and a half years. There were two deformities of the spine. One was at the junction of the lumbar and dorsal vertebras; the other in the upper dorsal region of the spinal column. There were corneal scars on both eyes. Subacute pleuropneumonia developed. The fluid withdrawn showed no tubercle bacilli. It would seem, from the history of this case that the cause was unquestionably tuberculosis, but no history of specific or tuberculous trouble could be obtained. Powers states that syphilitic disease of the spine sometimes occurs at two different points in the vertebral column, separated by one or more healthy vertebræ, while such healthy intervals less often occur in tuberculous diseases." Spinal disease, caries of the spine, tuberculosis of the spine or kyphosis is a disease common in childhood, and usually occurs between the first and tenth years. Statistics show the dorsal region more often affected. Double curvature is not common.

**Observations on the Diagnosis of Nasal Sinusitis.**—Walter J. Freeman states that one of the greatest hindrances encountered in reaching a correct diagnosis is the fact that the sinusitis very frequently occurs in the narrowest side of the nose. The writer says that in the diagnosis of antrum inflammation, whether acute or chronic, especially when there is only a small amount of discharge, no sign has stood him in such good stead as the discovery of pus flowing over the upper surface of the posterior end of the inferior turbinal. A tentative diagnosis is often made by certain well-defined odors, those of sour pus and of sulfuretted hydrogen. These odors are very different from that found in antrum suppuration due to genital caries, the latter being more foul and clinging. The symptom of intermittent cacosmia is very significant of sinus suppuration, and the antrum will usually be found to be the cavity affected. While acute inflammation of the ethmoid sinuses is very common in grip epidemics, the writer has never yet seen a case in which appropriate local and constitutional treatment did not effect complete resolution within a few weeks. Except in atrophic rhinitis or in rare cases of deformity of the septum with accompanying lack of development of the turbinals, the direct flow of pus from the sphenoid opening can seldom be seen. When the discharge is abundant and the turbinal swollen, a positive diagnosis of the special cavity affected is at first often impossible. Contraction by cocaine and syringing will finally allow a fairly accurate diagnosis. In cases of small amount of pus, examination should be made either early in the morning before the sinus has emptied, or late in the evening when the sinus, drained, it may be, during the night, has had a chance to refill.

*The Lancet, July 4, 1903.*

**Hypertrophy of One Breast.**—The case is reported by J. R. Gibson, his patient being a woman of twenty-five years, in her first confinement. She stated that at puberty the left breast had grown so much more rapidly than the right that a pad was required over the latter to give the bust a symmetrical appearance. No trouble was caused by this size except annoyance from weight. Both mammæ were well-shaped and both secreted well after confinement, especially the larger one, which, from its feel, appeared to be composed mainly of glandular tissue.

**Perforations of the Gall-bladder; Treatment by Invagination.**—Influenced by the recent advice of a colleague who advocated the invagination method of closing perforations of the bowel met in cases of strangulated hernia, H. A. Lediard has applied the method to perforations of the gall-bladder, and gives the operative details of a successful case. At the operation the viscus was discovered in a mass of matted omentum, with a gangrenous-looking perforation on the anterior surface near the fundus. A gallstone of small size was seen lying outside the gall-bladder. After the bile had been removed with swabs the perforation was enlarged with scissors and removed thirteen small gallstones, the gall-bladder packed with gauze, and the abdomen cleaned. The perforation was invaginated and stitched with Lembert's sutures, one suture passing through the edge of the liver, owing to rottenness of the gall-bladder wall. The entire abdomen was now flushed out with salt-solution, and the wound was then closed absolutely. The patient suffered from shock and had a subnormal temperature for a few days and was fed rectally for some five days, but made a good recovery.

**The Influence of Diet in Pregnancy on the Weight of the Offspring.**—From dietetic experiments on guinea-pigs, D. M. Paton concludes (1) that the weight of the young is independent of their number, and (2) that the weight of young produced in well-fed guinea-pigs bears a close relation to the weight of the mother. His observations, though few in number, warrant the statement that the size of the offspring depends very directly upon the diet and nutrition of the mother during pregnancy. While this explains the easy labors among the healthy lower classes and confirms Prochownick's conclusion that by dieting the mother the children of rickety women may be so reduced in size as to be viable, it also probably helps to explain the very high infant mortality among the very poor. The infant starts life at a low level and readily succumbs to the hardships to which it is too often subjected. It is also logical to believe that the nourishment of the maternal tissues seem to take precedence over the nutrition of the fœtus. Were this not the case, had the embryo the prior claim to nourishment, we should find that in badly nourished mothers each gram would produce a greater proportionate weight of young than in well-nourished mothers. This is exactly the reverse of what occurs. The mother thus appears to pass on the *surplus* nourishment to the fœtus, and the better the nutrition of the maternal tissues, the greater is the growth of the young in utero.

**The Fatal Effects of Chloroform on Children Suffering from a Peculiar Condition of Fatty Liver.**—The argument of L. G. Guthrie is to maintain the proposition stated in the title of his paper. The clinical histories of several cases are given together with the autopsy findings. The sequence of events is assumed to be as follows: (1) The liver being previously to the operations in an advanced state of fattiness was probably on the verge of functional inadequacy with regard to elimination of toxins entering the portal circulation, though still able to hold its own in ordinary circumstances. (2) Chloroform by decreasing oxidation already deficient aggravated the condition of fattiness already present and so lowered the hepatic functions that ptomains or toxins escaped into the general circulation. (3) Chloroform, moreover, by its specific action on the kidneys, prevented the elimination of such poisons by the urine, and was thus again immediately concerned in the cause of death. In regard to the mode of action of chloroform in these cases the toxæmic theory may be safely regarded as the true one, the theory of fat embolism having been disproved. Concerning the diagnosis of the peculiar liver condition, Guthrie declares it is not difficult if the peculiar character of the cerebral symptoms is borne in mind. The screaming and delirium so often noted should not be mistaken for the fractiousness of a child in pain, or when "feeling sick." Jaundice is an indication of danger. In case the latter is imminent, purgation, venesection, and saline transfusion are the only procedures offering any valid hope of success.

*British Medical Journal, July 4, 1903.*

**Smallpox and Revaccination.**—John Marshall Day reports two cases: One patient, sixty-six years old, was last in contact with a case of smallpox on May 26. She was successfully revaccinated on that date, but on June 9—that is, on the fifteenth day, including both dates—she was suffering from a smallpox rash in the early stage. Another case last in contact with smallpox on May 8, successfully revaccinated on that date, first seen on May 22 with commencing smallpox rash—that is, on the fifteenth day. It is necessary to keep contacts under observation for at least fifteen days.

**The Life-span of Filaria Medinensis.**—Patrick Manson says that the annual recurrence of a guinea-worm season in some of the endemic districts affected by that parasite suggests that at least one year, less three to six weeks, necessary for the preparatory metamorphosis in cyclops, must elapse between the date of infection of the human test and the appearance of the mature embryo—emitting worm at the surface of the body; and further, that the season of infection is correlated to an annual recurrence of certain hydraulic and thermic conditions favorable to cyclops and to the evolution of the parasite in that crustacean. But it is hard to prove this incontrovertibly from observation in the endemic regions, seeing that it is generally impossible in these localities to exclude the possibility of the infection having taken place at some date prior to or subsequent to the commencement of the postulated year.

**Remarks on Cancer of the Prostate and the Selection of Cases for Suprapubic Prostatectomy.**—Reginald Harrison says that carcinoma of the prostate in by far the greater proportion of cases is of a hard and slow-growing nature, closely resembling schirrhus of the breast, both microscopically and to the naked eye. As a rule, there is not very much intravesical projection of the prostate in these cases, and what there is is of an uneven and irregular outline. On the other hand, the large, soft adenomatous prostate presents, as a rule, a considerable enlargement into the bladder cavity with smooth rounded

surface. The writer lays considerable stress on the importance of recognizing carcinoma or cancer of the prostate when it is the cause of the enlargement, and distinguishing it from ordinary hypertrophy or adenoma, for the reason that it may be little short of a calamity to submit a person to a prostatectomy should the enlargement turn out to be of a malignant nature without knowing it. The prostate is approached operatively, much on the same principle as the breast and other organs of the body. It is most important to recognize, first, the precise nature of the enlargement to be dealt with. Though a deliberate prostatectomy may not be advisable in cases of this kind, there can be no doubt that carcinoma of the prostate often, sooner or later, leads to conditions in which operative interference is called for, the writer refers more particularly to the effects of obstruction so caused upon the contents of the bladder. A suprapubic opening may give immense relief to the patient whose bladder is distended with clots or foul urine. This is a substitute for a catheter which may be advantageously utilized. The writer then adds a word about the Röntgen rays, and high-frequency currents in some of these inoperable cases of prostatic carcinoma. He thinks this method is worth a trial. Partial operations on the prostate are not to be recommended when the entire organ is more or less involved in a hypertrophy.

*Münchener medicinische Wochenschrift, June* 23, 1903.

**Treatment of Laryngeal Tuberculosis by Galvanopuncture.**—L. Grünwald recommends this method from an extended clinical experience. Its value depends upon the fact that by means of the puncture the treatment is carried to the deeply infiltrated tissues, and it has long been recognized that unless these are reached permanent results are not obtained by any method. Futhermore, galvanopuncture does not irritate the healthy mucous membrane surrounding the tuberculous lesion and consequently does not produce the annoying and baneful disturbances arising from most local applications. In using this method the tissues to be punctured are first anæsthetized, and then the small platinum point of the cautery, at white heat, is pressed into the tissue until the healthy portion is reached; this is determined by a feeling of resistance which is encountered the moment that sound tissue is reached. The entire puncture takes from five to ten seconds. Three or four punctures are thus performed at one sitting, and four to six sittings are usually required to treat thoroughly all the diseased tissue. Two illustrative cases are appended.

**Tar as a Covering for Streets.**—M. Schottelius and Guglielminetti advise the covering of streets with coal tar so that the dust nuisance and its harmful consequences may be abated in great measure. In several places, notably Monaco, Paris, and London, raw petroleum has been used for this purpose, and while thereby the "dust plague" has been greatly lessened, it cannot be said to have been a successful method because of its non-durability, since it only lasts for about six or eight weeks. In addition to this, it is very expensive. The use of coal tar for the same purpose is, as recent experience has shown, very much more satisfactory because of its cheapness and durability, since it remains in good condition for at least eight months, even if the streets thus treated are used for a heavy traffic. In its application the following principles must be observed: (1) It must only be applied during dry warm weather, and the streets should have been perfectly free from moisture for two or three days previous to the commencement of the work. (2) If the streets to be treated are macadamized they must be in good condition and present an even hard surface. (3) At the time of the application the street must be absolutely dust free. This is to be obtained by having them wetted down and quickly dried on a warm clear day. (4) As soon after the wetting as the street has dried the coal tar heated to 60° C. is applied with brushes in an even layer about 1 or 2 mm. thick. Upon this a small quantity of sand is sprinkled. This hastens the drying of the coal tar and a shiny slippery surface is avoided. If the work has been done as above described, in the morning the street may be opened for traffic on the same evening.

*French and Italian Journals.*

**The Anti-tuberculous Vaccination of Nursing Infants.**—M. Behring and M. Hericourt proposes to immunize infants by feeding them on milk taken from cows that have been vaccinated against tuberculosis, old bacillus cultures of human origin having been injected in small doses in young animals. Experimentation has shown that animals so treated are absolutely immune. There is, of course, no danger in trying the process on infants, but as all children do not become affected with tuberculosis, it will be difficult to tell whether or not they owe their immunity to the treatment.—*Journal des Praticiens*, April 23, 1903.

**Experiments in Regard to the Diazo-reaction of Ehrlich.**—The following are some of the results obtained by Carmelo Di Bernado. The reaction was absent in nearly all of thirty-seven malarial patients. Out of 262 tuberculous patients, it was absent in almost all cases of early pulmonary tuberculosis; while it was present in the second and third stages. The reaction and its intensity were not in relation with the temperature, the condition of nutrition, the number of bacilli in the sputum, nor with diuresis nor diarrhœa, but rather with the extent of the pulmonary lesion. In pleurisy, peritonitis, meningitis, adenitis, and in osseous tuberculosis, it is a valuable means of diagnosis, and it disappears if recovery ensues as a result of medical or surgical treatment.—*La Riforma Medica*, June 17, 1903.

**Lesions of the Kidneys and Stomach in Chronic Lead Poisoning.**—P. Menetrier concludes from his researches that the chief characteristic of the kidney lesion in these cases is an atrophic sclerotic nephritis from vascular hypertension, and not an excretory nephritis. The gastritis, while possessing in common with ordinary gastritis the usual lesions, such as glandular atrophy with a diminished number of glands, and a tendency to the multiplication of their culs-de-sac, changes in the epithelial lining, disappearance or diminution of the differentiated cells, is in addition characterized by the presence of a regular intertubular sclerosis, diffused and generalized in the gastric mucosa, which is slightly thickened, while the submucous and muscular coats are not modified. This interglandular sclerosis pushes up and between the glands in the form of fibrous bands. In all other particulars the gastritis of chronic lead poisoning resembles that of alcoholic poisoning with which, indeed, it is often associated.—*La Tribune Médicale*, June 24, 1903.

**The Prophylaxis of Malaria by the Administration of the Salts of Quinine.**—Joseph Michon experimented in the most malarious part of Corsica, administering quinine to thirty-eight vintagers in the hope of preventing the malaria to which they were usually subject. The dose was 0.80 gram of the hydrochlorate of quinine every three days, in two doses, one in the morning, and one in the evening. The next year he diminished the dose slightly. In the first year there was not one case of fever. In the second one woman only was attacked, once only, and that not severely. The workers experimented upon slept in the open air, on account of the insufficiency of dwelling houses. The season and the locality were the worst possible so far as regards infection, and yet the patients were immune. In a neighboring town, where the conditions of existence were exactly the same, many of the vintagers had malaria, and not a few succumbed.—*Archives Générales de Médecine*, June 23, 1903.

**Meningeal Symptoms Occurring During the Course of Gastroenteritis in Children.**—When symptoms pointing to a lesion of the meninges occur during gastrointestinal attacks, observes A. Ausset, it is of the utmost importance that we should be able to tell whether or not meningitis is really present. In his opinion, simple convulsions, not followed by special meningeal symptoms, are usually, if not always, due to some irritation of the meninges of more or less severity; the child may later be attacked by encephalitis, cerebral sclerosis, hydrocephalus, etc., definite lesions which prove that the convulsion was the sign of some grave change in the nerve centers. Diagnosis of the true state of things is, however, extremely difficult, nor can lumbar puncture be relied upon to give us absolute information. Kernig's symptom is almost always present and gives valuable indications. Ocular troubles are of great diagnostic importance, but they do not occur when there is merely hyperæmia, congestion of the meninges. Still a maximum contracture of the pupils is a frequent sign. As regards treatment, lumbar puncture may be of use in allaying pains, in diminishing hydrocephalus when it is present, and in assisting in the diagnosis. It must, however, be done under the strictest antiseptic precautions, and not be resorted to unless clearly indicated, nor repeated too often.—*L'Union Médicale du Canada*, June, 1903.

**Whimpering and Crying in General Paralysis.**—M. Marandon de Montyel has observed a tendency to whimper in more than one out of every three paralytics. Syphilitics and alcoholics were the most frequently affected with this tendency, and it lasted longer than in others, but was of a moderate degree, while in other non-infected patients it was always present in an excessive degree. In frequency and in duration it was in direct relation to age, and in intensity in inverse ratio. It was more frequent and more intense in winter than in summer. It was especially associated with motor troubles. No relation was established between whimpering and hyper-

**æsthesia**, but it was found to be in inverse ration to genital changes. The usual duration of the symptom is from two to three months, but in many cases it lasted only a fortnight.—*Le Bulletin Médical*, June 24, 1903.

**The Cytological Study of the Cephalorachidian Fluid in Some Diseases of Childhood.**—Mario Flamini has found that when there is meningeal irritation, leucocytes are present in large numbers in the cephalomeningeal fluid. In tuberculous meningitis lymphocytes are in preponderance, yet in some cases polynuclears are the more numerous; the latter is the case when the Koch bacillus is found in the fluid. The bacilli of tuberculosis with their proteins exercise a positive chemiotaxic influence on the large leucocytes, their toxins on the other hand, exert their influence on the lymphocytes. The meningeal processes may generally be divided into two classes—those in which the irritation is due to toxic substances of different natures, and those in which it is due to the action of germs. It would seem, from the results of experimentation, that in the former cases lymphocytes, and in the latter polynuclears, prevail. The value of cytodiagnosis as a means of distinguishing between tuberculous meningitis and that due to other infective agents loses much of the value which of late has been attributed to it.—*Rivista di Clinica Pediatrica*, June, 1903.

**A Myotoxic Serum.**—Francesco Scotti, from his experimentations, concludes that (1) The injection of the muscular juice of the rabbit into the peritoneum of a duck, and a guinea-pig, will give us a serum which will be toxic in its action toward the rabbit. (2) This action is both general and specific. (3) The general action, most intense in the serum of treated guinea-pigs, may cause almost immediate death of a rabbit. (4) The specific toxic action is manifested after small doses in an increased excitability of the muscular system. (5) The serum of an untreated guinea-pig not only does not possess this property, but, on the other hand, produces a certain lowering of muscular excitability in rabbits.—*Giornale Internasionale delle Sciense Mediche*, June 15, 1903.

**Gastric Opotherapy with Pig's Gastric Juice.**—Maurice Hepp has used this substance with a fair amount of success in the treatment of certain infections of the digestive tract, and with very little success in cases of mucomembranous enterocolitis, but he has had really remarkable results in cases of pulmonary tuberculosis. In the early stages of the disease, pig's gastric juice administered in doses of several tablespoonfuls a day, completely overcame the lack of appetite and the sense of heaviness which so often prevent tuberculous patients from obtaining the nourishment which they so much need. The most striking effects, however, were produced in advanced and almost desperate cases. Frequently the administration of this remedy stopped the incessant vomiting, stopped the gastric pain, and calmed the attacks of cough of gastric origin. The author supposed at first that these were accidental effects, but repeated observations have convinced him that they were really due to the medicament.—*Gazette des Hôpitaux*, June 18, 1903.

**Reunion of the Severed End of a Finger One Hour and a Half after the Accident.**—H. Secretan describes the case of a young woman who came to him with a wound of the left middle finger. The end had been cleanly severed by a cutting machine at about the root of the nail. While the author was examining the finger, a friend of the young girl took the cut end from her pocket where it had been lying wrapped in a piece of newspaper. The accident had occurred an hour before, and all that time the cut end, which had been picked up from the dusty floor, had been lying in the pocket in an unclean piece of paper. Nevertheless, yielding to the patient's desire, the author attempted to graft it to the finger. The cut end was immersed in tepid water, and then fixed in place with three stitches, one deep one in the pulp, and two extremely superficial lateral ones. The result was excellent. A very small spot of necrosis formed near the deep suture. The circular wound healed by first intention in ten days. The patient returned to work in less than a month.—*Revue Médicale de la Suisse Romande*, June 20, 1903.

---

**Puerperal Sepsis.**—When a case of uterine sepsis progresses unfavorably after curetting, irrigation, and proper general treatment, as evidenced by the pulse, the temperature and the condition of the uterus, we are justified in opening the abdomen and removing the uterus, unless, after opening the abdomen, we find some condition outside of the uterus to account for the persistence of the sepsis, or if we find some condition in the uterus itself, as a single intramural abscess or a localized gangrene, which would admit of removal without ablation of the whole organ, as in cases reported by Hirst and myself.—H. N. Vineberg.

## Therapeutic Hints.

**Infant Laxative.—**

| | | |
|---|---|---|
| ℞ | Senna | gr. viii |
| | Pumpkin seed | gr.i. |
| | Wormseed | gr. i. |
| | Sodium bicarbonate | gr. ss. |
| | Rochelle salt | gr. ii. |

For dose.

**Mercury.**—It is generally accepted that the best method of using mercury in lues is by inunction and fumigation. If a bag containing blue ointment be worn around the neck so as to hang upon the breast, the warmth of the body will vaporize the mercury, part of which is inhaled, and part absorbed by the skin. In this way most of the objections to fumigations and inunctions are avoided, and the effect is quite readily secured. —Welander.

**Prurigo of Hebra.—**

| | | |
|---|---|---|
| ℞ | Camphor | gr. xii. |
| | Oil of cade | gr. xv. |
| | Sulphur | gr. viii. |
| | Oil of chaulmoogra | gr. iii. |
| | Vaselin | gr. lxii. |

—Baissade.

**Lichen Pilaris.**—Pumice soap, marble powder, more or less fine, black soap, or salicylic soap, applied with friction, will remove the roughness of the skin. For the resulting inflammation the following are recommended:

| | | |
|---|---|---|
| ℞ | Ungt. zinci oxidi | 100.0 |
| | Resorcini | 3.0 |
| | Sulph. sublimatis | āā 5.0 |
| | Ichthyol | āā 5.0 |
| | Talci venetii | āā 5.0 |

**Dont's in the Hydriatic Management of Fevers.**—Don't bathe in cold water to reduce fever, but to refresh the fever-stricken patient. (2) Don't permit cyanosis or chattering of teeth. Stop! (3) Don't stop bathing because patient complains of chilliness. (4) Don't raise temperature of baths on account of chilliness. Shorten bath and increase friction. (5) Don't neglect friction during every cold procedure; it prevents chilling. (6) Don't disregard the fact that the Brand baths at 65° to 70° is the ideal bath for typhoid fever. (7) Don't use the Brand bath in a bathroom. (8) Don't give up bathing because the ideal bath is not procurable. Other procedures are useful. (9) Don't use ice-coil to abdomen. It has no refreshing effect and renders skin cyanotic beneath it. (10) Don't lose sight of the fact that the chief aim of all cold procedures is reaction. —Simon Baruch.

**To Cleanse Hypodermatic Needles.**—If neglected so that the wire cannot be passed, the point may be heated in an alcohol flame to burn out the organic matter. When the wire is rusted in the cannula, the latter should be allowed to soak over night in neutral oil, and then heated as before. After that, all traces of rust are removed by forcing into the point more oil.

**Decinormal Sal-solution.—**

| | | |
|---|---|---|
| ℞ | Calcium chloride | gr.iij ℈ |
| | Potassium chloride | gr. jss. |
| | Sodium chloride | ʒijss |
| | Aqua dest q. s. ad | Oij |

M.: This may be injected subcutaneously, into the intestine, or into a vein. —Lock.

**Urticaria.—**

| | | |
|---|---|---|
| ℞ | Alcohol | |
| | Chloroform | |
| | Sulphuric ether | āā ℥ss |
| | Menthol | gr. 150 |

M. S.: To be applied with an atomizer.

—Gaucher.

**Tinea Tonsurans.—**

| | | |
|---|---|---|
| ℞ | Sodii borat. | ʒi. |
| | Spir. camphoræ | ʒi. |
| | Glycerini | ʒii. |
| | Aq. aurantii flor. | ad ʒiv. |

M. ft. lot. S.: Apply twice daily.

**Furunculosis.—**

| | | |
|---|---|---|
| ℞ | Sodii boratis | |
| | Acid. borici | |
| | Acid. salicylici | ʒi |
| | Acid. Tannici | āā |

M. S.: Sprinkle upon yeast poultice and apply.

# Book Reviews.

A Textbook of Legal Medicine and Toxicology. Edited by Frederick Peterson, M.D., etc., and Walter S. Haines, M.D., etc. In two volumes. Vol. I. Philadelphia, New York, and London: W. B. Saunders & Co., 1903.

Within the past decade there has been a remarkable awakening of interest, especially in this country, in regard to the subject of legal medicine, and it is scarcely ten years since two large and important treatises appeared almost simultaneously; one in four volumes by Witthaus and Becker, and another by Hamilton and Godkin in two. It would therefore seem as if the traditional "want" had been fully met by these works, and which are generally regarded as standard authorities.

Drs. Peterson and Haines in seeking for a *raison d'être* for a new textbook, the first volume of which has just appeared, claim that there is still a place unfilled by the smaller textbooks, or by the "Systems of Encyclopedic Dimensions." Perhaps unconsciously, nevertheless they have followed in the steps of Hamilton and Godkin, for the result is a remarkably close copy of the latter well-known work. Not only is the new textbook a counterpart in size, but the unusual and novel arrangement of subjects and titles and the make-up of the older work are in large part adopted. The editors have, even in a questionable spirit of enterprise, impressed into service some of the contributors to the earlier books, whose new articles very closely resemble those they have already written. Upon the principle that one cannot have too much of a good thing this does very well, and is an evidence of the sincerest flattery, yet it is not difficult to detect a great deal of repetition, and much use of well-worn material which cannot help but be the case under the circumstances.

The fresh blood that has been infused into the collaboration is in some instances stimulating and welcome, and examples may be found in the original articles upon the effects of lightning and electricity, and a section upon the destruction of the human body by fire and other agents for the purpose of criminal concealment, which was evidently inspired by recent Chicago and Philadelphia murder cases.

From the reputation of Dr. Frederick Peterson as a teacher and student of mental disease one would expect that the article upon insanity would be from his pen and quite abreast with the psychiatry of to-day, which it is not in any sense, and besides, it is bare of medicolegal information. The editor contents himself with presenting an article upon the stigmata of idiocy and degenerative affections, most of which, including the cuts, has appeared in his other writings.

Though more properly belonging to a treatise on neurology, the section upon speech disorders is scholarly and well written, and the diagrams are ingenious, original, and helpful.

Dr. Langdon goes much further than most modern writers do in his amplification of aphasia, rivalling in completeness the classical article of Kussmal. It is to be regretted that the contributor of the section upon the "signs of death" did not have that upon "post-mortem examination" assigned to him as well instead of that upon "Identity," which lacks originality and shows effort.

Dr. Ewings' well-known reputation as a pathologist is increased by his careful consideration of the changes that take place in the dead body, especially in connection with microscopical and bacteriological findings. Balch's essay is a close copy of one written by him for another publication to which reference has already been made, and in a way the same may be said of Chaddock's "Sexual Paræsthesia."

A fault common to all of the recent encyclopedic treatises lies in the fact that but few of the writers seem to have had the requisite experience in court, or a knowledge of jurisprudence that fits them to deal with the legal aspect of the subject. Perhaps the forthcoming articles of Drs. MacDonald and Haines, both of whom are well-known experts, will make up for this so far as the subjects allotted to them is concerned. The book, from a mechanical standpoint, is very creditable to the publishers, although the impression is conveyed that it was prepared largely to utilize some excellent chromolithographs of Hoffmann that have done service in another publication of this enterprising firm.

More Light on a Dark Subject. By Dr. J. R. Bailey, 1903.

This book is not intended for the physician, but as a means of educating the laity on sexual matters. The effort is made to place the subject on an every-day basis, and by plain, simple language to inculcate the truth that there is nothing impure in nature. No one familiar with the facts will deny that such instruction is sorely needed, and that it may be made a valuable ally to the family physician. Our author is evidently an osteopath, for he occasionally indulges in a glowing description of what osteopathy can accomplish, and apparently gives both his enthusiasm and his imagination a loose rein in describing its achievements in mitigating the pangs of labor. On the whole, the book is wholesome in tone and its advice is sound, but the reader is constantly annoyed by the numerous typographical errors that mar almost every page.

Post-mortem Pathology. A Manual of Post-mortem Examinations and the Interpretations to Be Drawn Therefrom. A Practical Treatise for Students and Practitioners. By Henry W. Cattell, A.M., M.D., Pathologist to the Philadelphia Hospital and the West Philadelphia Hospital for Women, etc. With 162 Illustrations. Philadelphia and London: J. B. Lippincott Co., 1903.

This is one of the really good medical books of the year, and one that will undoubtedly find a large and appreciative circle of readers. There are few practitioners who do not from time to time have to make autopsies, and for whom a careful exposition of the various methods to be employed, particularly under the often hampering restrictions of private work, would be most useful, while the thoroughness and theoretical completeness of the work cause it to fulfil the needs of the trained pathologist as well.

The author combines great breadth of scientific attainment with much natural fertility of invention, and this latter trait is constantly appearing in the hundreds of little wrinkles suggested for overcoming difficulties. Features of especial interest are the descriptions and plans of autopsy rooms, tables, and refrigerating plants, the chapter on post-mortem instruments and how to use them, and post-mortems on the new born. An excellent chapter on comparative postmortems gives directions for the section of the horse, cow, and smaller domestic animals, as well as on the birds and rodents used in the laboratory.

The important subject of the medicolegal aspects of the pathologist's work is adequately discussed, and detailed directions are given for the performance of autopsies when legal complications are to be expected. The illustrations throughout are of the highest order and are well chosen, while the author's simplicity and directness of style, together with the thoroughly modern nature of his teachings, as exemplified by the sections on cryoscopy and agglutination diagnosis of human blood, combine to make a book of the greatest interest and value to every one connected with the study of medicine.

La Pratique des Autopsies. Par M. Letulle. Paris: C. Naud, 1903.

This book, which has just appeared, incorporates the experience of well-nigh thirty years of Professor Letulle's activity as a pathologist and teacher at the medical faculty of the University of Paris. Since the appearance of Virchow's book nothing has been given to the medical profession on this subject surpassing Professor Letulle's "Practice of Autopsies." It is both a textbook for physicians and students and an admirable guide to teachers of pathology.

The first portion describes the instruments necessary to make, and the general technique to be pursued in making, an autopsy. Next comes a table giving the average weights and dimensions of the organs of the body according to various authors and according to the writer's own experience. The second portion treats of the external aspect of the body, the opening of the cavities, total evisceration, methodic isolation and the examination of of all the internal organs. The third portion is consecrated to the examination of the circulatory and respiratory organs, the digestive tract and its annexes, of the sexual organs, and the nervous system. The fourth portion of the work speaks in detail of the autopsies of new-born children and of women who have succumbed to puerperal fever. The last chapter gives most important suggestions regarding medicolegal autopsies.

In conclusion we should like to give Professor Letulle's strong arguments for the necessity of autopsies. He says "an autopsy is necessary for three reasons: first, for social; second, for medicolegal; and third, for scientific reasons. Its practice protects the community at large and also the individual. In order to perform a scientific autopsy which shall be of value in legal medicine, a methodic practice, a thorough knowledge of pathology, and a wide experience are indispensable."

We recommend Professor Letulle's book to all teachers and pupils of pathology and to all physicians who may be called upon to perform autopsies. We cherish the hope that the work may soon be translated into English.

# Society Reports.

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held June 3, 1903.*

CHARLES N. DOWD, M.D., PRESIDENT.

**Stomach and Intestinal Crises.**—Prof. C. A. EWALD of Berlin read this paper. He said that his paper would be confined to a consideration of those crises of the stomach and intestine associated with spinal sclerosis or tabes, and that he would exclude those forms of crises occurring in gallstone and kidney stone disease, ovarian pain, etc. Although other writers had spoken of gastric crises previously, Charcot was the first one to formulate them. In eighty-nine cases of gastric, seen in the last ten years, early symptoms of tabes could be demonstrated. In sixteen of the cases syphilis was believed to be the cause. The average interval between the crises was two years and ten months, and the shortest interval, two months. Toward the end of the disease the attacks occurred every day. In some cases they would be prolonged for two or three weeks. These crises generally began with cramps in the epigastrium, followed by nausea and vomiting. At first the vomitus consisted of food particles that were in the stomach; later, of bile and mucus, and sometimes blood, but Dr. Ewald said that he had only seen four cases of the last type. In some of the rarer cases the attacks came on slowly when the stomach was empty, the pain became more intense and was followed by vomiting and vertigo. The character of the attacks might change even in the same individual. In one case under observation there had been five attacks in five years. In these cases tabes developed very slowly. Sometimes the attacks increased in severity. At first, gastric crises were supposed to be due to an increased amount of hydrochloric acid, but they were now known to be associated with a subacidity. He had observed ninteen cases in which subacidity largely prevailed. During these attacks, in a number of cases, no hydrochloric acid was present. The bowels were generally constipated; he had only seen two cases with diarrhœa.

Intestinal and anal crises were much less frequent than gastric crises. In the former the abdomen became as hard as a board and there was pain, sometimes in the ileocæcal region. In addition, there was a great desire to go to stool, but without result, the highest degree of constipation being present. In the interval of the attacks the abdomen was normal. In anal crises there was exquisite pain in the rectum and anus, described by the patient as like an iron being twisted around inside the rectum. The diagnosis was often difficult. Cases of nervous or paroxysmal vomiting were difficult to differentiate from those cases of vomiting occurring in sclerosis of the spinal cord, but the nervous vomiting did not occur at any particular time, was often seen in young girls during menstruation, occurred at certain seasons of the year and was not accompanied by disease of the spinal cord. Attacks of gallstone and kidney stone colic simulated these crises. A case was mentioned in which an operation for stone was done, but the case proved to be one of gastric crisis associated with tabes. In another case an operation for gastric ulcer was done, and in still another the ovaries were removed. The autopsy showed tabes to be present. With regard to the cause of these crises Dr. Ewald said that we were absolutely in ignorance. The sympathetic nerves were involved, and there was atrophy at the root of the vagus and laryngeal nerves, but this did not throw much light on the etiology. It was probable that some special stimulus must be present, as in epilepsy. The treatment depended upon the disease present. If syphilis or any cerebrospinal disease were the underlying condition, it should be treated. There was no known method by which the attacks could be cut short. In grave cases morphine might be given in increasing doses, or the physician might make use of Corning's method of injecting cocaine into the spinal canal. General hygiene and general tonic treatment, such as the administration of iron and arsenic, were recommended. The bromides were also given for their sedative effect.

Dr. Ewald closed with a few remarks concerning this country, his pleasant reception and sojourn here, and the hospitality that had been extended to him.

Prof. HERMANN TILLMAN of Leipzig was the next speaker. He said that he had been so overwhelmed with our delightful hospitality that he had been unable to do any scientific work, and consequently had not prepared a paper. He was very much interested in our hospitals and scientific work, for science and art were international. He hoped that Germany and America would always be found working together harmoniously. He would go away from America a better surgeon and stimulated to do better work, and would always look back upon this visit with the greatest pleasure.

Dr. D. B. ST. JOHN ROOSA said that in the early days in New York the great source of medical information was found in the schools of Amsterdam. Some time later the Scottish schools came into prominence, and Edinburgh became the center of such learning. After this came the French era, under Laennec and Trousseau, and still more recently the happy era when the student went to Germany. As representing the oldest medical society in the State of New York, which stood for knowledge and truth and interest across the sea, he wished to welcome these guests, and he would look forward to the day that would bring them here again.

Dr. FRANK VAN FLEET, after commenting upon the cordiality displayed in this city toward teachers from Germany and other countries, he moved a vote of thanks to Drs. Ewald and Tillman. After the meeting adjourned an opportunity was afforded to meet these guests socially.

---

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held June 4, 1903.*

CHARLES L. DANA, M.D., VICE-PRESIDENT, IN THE CHAIR.

**In Memoriam: Dr. T. Gaillard Thomas.**—Dr. HENRY D. NICOLL delivered this address. (See Vol. 63, p. 1015.).

**A Study of Good Results in Hip Disease.**—Dr. VIRGIL P. GIBNEY was the author of this paper. He said that in making the diagnosis of hip joint disease the history was quite important, and one should not be satisfied with anything short of a thorough examination of the nude patient placed on a table. Among the early symptoms a more or less persistent limp was perhaps the most important. An *x*-ray examination could only be considered as an aid to diagnosis. A good result, from the practitioner' sstandpoint, was an arrest or termination of the disease regardless of the position in which the limb was left. It also implied that locomotion was not seriously impaired. He had seen very many instances in which the patient had not been satisfied with the result, and had sought aid from a general surgeon, with the result that an osteotomy had been done and the limb placed in a straight position. Invariably it was found that the deformity was not corrected. Surgeons who claimed that early excision yielded good results were not able to furnish proof of such statement. Excision was not popular in this country because of the mortality and the lack of stability of the limb. There was a growing tendency here to remove a small section of diseased tissue, the presence of which had been detected by an *x*-ray examination. It had been abundantly proved that the best results were obtained by the early and long-continued use of braces, irrespective of that bugbear, muscular atrophy. A satisfactory

result was one in which there was a minimum of shortening without deformity and a maximum range of motion. It was reasonable to expect that in the future earlier and more effective treatment of these cases would be possible, and that the results would consequently be better than now.

Dr. A. JACOBI thought orthopedic surgeons were prone to pay too little attention to the medicinal treatment of tuberculous bone and joint disease. Phosphorus would certainly improve a subacute or chronic osteitis. He was positive that a large number of cases of tubercular arthritis had been greatly benefited by such medication. He could not speak so favorably of arsenic, though it seemed to be beneficial. In general tuberculosis and in joint tuberculosis he was positive that creosote, or still better, guaiacol, did a great deal of good. The hygienic treatment should, of course, not be overlooked.

**Facial Irritability in Mental and Nervous Diseases.**—Dr. CHARLES L. DANA presented in abstract a paper that he had prepared on this subject. He said that the facial muscles were very delicately innervated, and that the sphincter of the eye and of the mouth were in a state of physiological hypertonus. Many muscular contractions could be obtained under normal conditions, by striking with a rubber hammer upon certain points on the muscles of the face. Many additional muscular responses could be elicited in those suffering from various mental and nervous diseases. Pathological studies indicated that most of these were direct or indirect muscular responses and not reflexes. There were, in reality, only two true reflexes of the face; one, the supraorbital reflex, which was generally present, and the other, the nasomental, which was rarely present. He had come to the conclusion that the facial irritability was certainly very much increased in the psychoses, *e. g.* melancholia, mania and paresis, and that as these conditions improved there was less facial irritability. In two cases of coma that he had recently examined all of the reflexes were very much exaggerated in one case, and in the other case the reflexes were almost gone, thus confirming the idea that the psychical state had much to do with the facial irritability. In cases of facial tic one would expect marked facial irritability, but examination would show that they were not very different from the normal. In differentiating between a coma from hemiplegia and a toxic coma it was probable that these facial responses would prove of some value. The report on this subject was only a preliminary one, and intended to call attention to the possible value of these muscular responses of the facial muscles.

Dr. JOSEPH FRAENKEL said that his attention had only recently been directed to this subject. It was the general rule that the reflexes were exaggerated in lesions of the pyramidal tract, but this appeared to be the reverse with regard to the muscular responses of the face. In the few cases of general paresis that he had examined with reference to this point all of the muscular responses of the face were found to be decidedly exaggerated.

Dr. LOUISE G. ROBINOVITCH was disposed to think that the author had been too sweeping in his generalizations.

Dr. J. RAMSAY HUNT said that he had followed some of Dr. Dana's observations, and could confirm them. The fact that the nasomental response had been described as a not uncommon accompaniment of general paresis, seemed to him very important. He had himself found it in a number of cases of general paresis, and had been unable to find it in a number of other forms of nervous disease.

Dr. Dana, in closing, said that he had not attempted to draw inferences regarding his observations. Some care was necessary in eliciting these muscular responses. A rubber percussion hammer was a suitable instrument for this purpose. The temperament of some individuals was such as to seriously interfere with the attempts to elicit these responses unless the examiner exercised due care and attention to details.

### SECTION ON MEDICINE.

*Stated Meeting, Held May 19, 1903.*

LEWIS A. CONNER, M.D., CHAIRMAN.

**A Case of Supraclavicular Hernial Protrusion of Both Lungs.**—Dr. ALEXANDER LAMBERT reported this case and exhibited the patient, a woman of twenty-six years, who gave a history of marked anæmia last summer, and of a very severe bronchitis last January. During one of the attacks of severe coughing she experienced a pain in the left clavicle, which was followed by the appearance of a swelling. She then suffered a good deal from dyspnœa. Another attack of bronchitis came on, and a swelling appeared in the other supraclavicular space. This was her condition on coming under his observation: There was bronchovesicular breathing in these spaces, but no râles could be heard at any time, and percussion gave pulmonary resonance. The dyspnœa had gone, the swellings were distinctly less and the woman was quite comfortable. He was of the opinion that these swellings were due to protrusion of the apices of the lungs. Looking up the literature, it was found that three similar cases had been reported many years ago in persons suffering from emphysema. In 1873 a case of recurrent hernia of the lung had been reported, also in an emphysematous patient, and here the swelling disappeared at intervals and reappeared during severe spells of coughing. In one of two cases that had come to autopsy there was a bulging mass which had lost the usual appearance of the lung on section; in the other, the tumor presented more the appearance of lung tissue.

Dr. THEODORE C. JANEWAY said that if this were really a hernia of the lung it was difficult to explain the fact that there was no increase in size on coughing, and no evidence of expansive distension when pinched between the thumb and fingers. Again, he had never understood that the pleural membrane above the clavicle was sufficiently elastic to permit of so much distention, and rupture of the pleura would seem to be out of the question in this region. The appearance was very much like what he had seen in myxœdema, and percussion and auscultation yielded rather negative results. He, therefore, felt uncertain regarding the diagnosis.

Dr. C. CARMALT asked how this case was to be distinguished from what the French described as diffuse symmetrical lipomatosis. An example of that condition had recently been presented to the Surgical Section by Dr. J. F. Erdmann. The development of this lipomatosis was generally quite sudden, and such tumors were well known to transmit readily the sound of lung resonance. Anatomically, the apex of the lung and pleura was so reinforced by the muscles and vessels passing across the space that a hernia here must be quite a distinct mass. He would not be willing to accept the diagnosis without an exploratory incision.

Dr. LEWIS A. CONNER said he had previously an opportunity of examining this case carefully at some length, and he had been impressed not only with the absence of expansive pulsation but also with the fact that there was a very clear vesicular murmur transmitted through the mass, and apparently quite close to the ear. It was difficult to believe that this would be the case if the mass were one of fat. He was inclined to accept the diagnosis of hernia of the lung.

Dr. LAMBERT, in closing the discussion, said that in the case reported by Knox the pleura was found in the sac, and there had been hernial sacs of the neck found sufficiently large to admit three or four fingers. One reporter stated that a bright, shining membrane lined the sac, and that it was apparently the pleura. This established the possibility of the occurrence of such hernias. In three of the reported cases the tumors extended up almost to the ear under deep inspiration or

coughing; in the other three the condition was an exact counterpart of the case now under discussion. He saw no way of differentiating the condition from diffuse lipomatosis except by an *x*-ray examination, and such an examination was about to be made in this patient. At the first examination he had been disposed to think the tumor a lipoma. He had not been able to feel any impulse during coughing, and could only explain this by supposing that the hernial sac might be one having a narrow constriction.

**A Case of Beriberi of the Dropsical Form.**—Dr. L. A. CONNER presented this patient, a sailor, twenty-six years of age, who complained of swelling of the limbs and great weakness. He had previously been in exceptionally good health, and his family history was good. For the past six months he had been on a sailing vessel cruising along British West Africa, just south of Liberia. He had not been ashore much, but had been in communication wih the natives. No one else on the ship had been taken sick. Five weeks before coming to the hospital, and while at sea, he first noticed a swelling of the abdomen, and three days later, swelling of the ankles. The latter was accompanied by tingling and numbness. Within a few days he began to suffer from weakness and fluttering of the heart, and it became necessary for him to keep in his bunk. On admission to the Hudson Street Hospital the temperature was 99.8° F., respirations 24, and pulse 100. The physical examination of the lungs was negative, except that there was fluid over the lower part of the right side. The apex beat of the heart was in the fifth space, well outside of the nipple line, and it was diffused and weak. The abdomen contained no fluid. The spleen and liver were normal. There was marked œdema of both feet, legs and thighs, and sensation was normal except over the right foot, where there was a distinct diminution in tactile pain and temperature senses. The anterior tibial and peroneal groups of muscles showed a decidedly diminished response to the faradic current, but there was no qualitative or quantitative change in the reaction of the galvanic current. The urine was examined repeatedly, and was each time found to be normal. Examination of the blood showed 4,400,000 red cells, and the hæmoglobin 80 per cent., and the leucocytes 8,000—in other words, the blood was practically normal. After having been in the hospital thirty-six hours the temperature suddenly rose to 102.5° F., he began to cough, the sputum became rusty, and physical examination showed a small area of pulmonary consolidation high up on the right side. After about three days the signs and symptoms referable to this complication disappeared, and he steadily improved. The œdema disappeared within a few days, and with this the fluid in the right pleural cavity. At the same time the condition of the heart became better, and the pulse showed great variations in frequency. His eyes were examined by Dr. Cutler, who found both nerves hyperæmic and small linear hemorrhages extending outward in both disks. The fields of vision were normal, and vision itself was but little disturbed. The treatment had been purely symptomatic. The speaker said that the case was chiefly interesting from the standpoint of diagnosis. Beriberi was known to be endemic on the western coast of Africa, and some physicians who had had excellent opportunities for examining this disease, stated that it behaved like an infectious disease with a very long period of incubation. There were great variations in the type, and the dropsy in many cases was almost the only prominent manifestation. The cause of the œdema was still obscure.

Dr. W. L. BAUER said that he had seen, about one year ago, at the St. Vincent's Hospital a case of the relapsing form of beriberi. There was a clear history of a previous attack of the disease, and the erratic heart action was a prominent feature. In the case just presented there were several things lacking for a positive diagnosis.

Dr. Conner said that the excellent previous personal history of his patient and the absence of any other obvious cause for the dropsy seemed to him a strong point in favor of the diagnosis of beriberi.

**An Unusual Case of Hypertrophic Osteoarthropathy.**—Dr. B. ONUF reported this case and presented the patient. About thirteen years ago the patient noticed that the terminal phalanx of the middle finger underwent thickening; subsequently the thumbs and then the other fingers showed the same change. There had been no pain in the affected parts. Six or seven years ago most of the nails became yellow and began to break off in layers. There was no paræsthesia in the affected parts. There was no history of syphilis, and the examination of the lungs was negative. Skiagraphs of the hands and feet were exhibited, and showed a disappearance of the terminal phalanges. The speaker said he had taken great pains in this case to exclude both syringomyelia and tabes dorsalis. He had just learned that two similar cases were on record.

**Hypertrophic Osteoarthropathy of Marie, with a Report of Two Cases.**—Dr. THEODORE C. JANEWAY presented this paper. The first case was that of a man of twenty-two years, having a family history of tuberculosis. There was a history of having suddenly begun to spit up pus, and of having continued to do this at intervals for a long time. On examination, the enormous size of the hands and legs was noticed; also a fetid bronchitis and bronchiectasis associated with osteoarthropathy. The length of the arm was 26 cm., and the circumference, 10 cm. below the condyle, was 23 cm. There was scarcely any taper of the arm. The patient died about nine months later, but no autopsy was obtained. In the second case the illness dated back eight years, and there a history of abundant fetid expectoration from the first. For five years there had been short attacks of bloody expectoration at intervals of four or five months. He complained of dyspnœa, and pain in the right side of the chest, with cough and expectoration. On examination, he weighed 184 pounds; the finger ends were clubbed; the length of the arm was 27 cm. Physical examination showed fibroid induration of the lung. The bone lesions in these cases were sufficiently described by the term "osteoperiostitis ossificans." Pathologically there was no distinction between the cases in which no primary condition was found, and those which were evidently secondary to well marked suppurative processes in the lungs. The skiagraphs showed that the clubbing of the fingers was due to hypertrophy of the soft parts and not to the enlargement of the bones. The literature of the whole subject was reviewed and all of the recorded cases were classified. The total number of cases of undoubted osteoarthropathy was 94. Of the cases classified under this head, 28 were found to be really examples of ordinary clubbed fingers. Of the 94 cases, 65 were associated with disease of the lung or pleura. Suppurative and gangrenous processes were associated with 48 of the cases. That prolonged venous congestion was the cause of the ordinary clubbed fingers was generally conceded, and it was highly probable that local circulatory conditions had much to do with the development of osteoarthropathy, it being well known that venous stasis exerted a distinct influence on the growth of bone.

Dr. C. CARMALT said that he had seen three of these cases. In one of them, suffering from empyema, there were clubbing of the fingers and hypertrophy of the radius and ulna. Later on this patient, although known to be tuberculous, improved very decidedly under the salicylates.

Dr. B. ONUF said he had taken radiographs of five cases of well-marked clubbed fingers in tuberculous patients, and in none of them were well-marked changes in the bone of the terminal phalanges revealed.

## AMERICAN NEUROLOGICAL ASSOCIATION.

*Twenty-ninth Annual Meeting, Held in Washington, D. C., May 12, 13, and 14, 1903.*

(Continued from page 78.)

SECOND DAY, WEDNESDAY, MAY 13.

**Central Neurofibromatosis.**—This was a contribution to the study of tumors of the medullo-ponto-cerebellar angle, by Drs. J. FRAENKEL and J. R. HUNT of New York. Five cases were reported at length showing a common origin of the tumor from cranial nerve trunks. The writers concluded that the pathological structure of the growths is of a kindred nature—neurofibromatosis, pure or in various stages of metamorphosis and transformation. The locality is almost identical—the angle formed by the junction of pons medulla and cerebellum. Their symptomatology because of this localization is, in the essential features, analogous.

The certainty of localization, the essentially benign nature of the growths, their loose attachment to the meninges and nerve trunks, distinguish this group of intracranial tumors as a most favorable one for surgical intervention.

In view of all this, they find justification for the suggestion to assign a separate place to this syndrome in the group of intracranial tumors. The susceptibility of the cranial nerves to neurofibromatosis varies considerably. With the exception of the olfactory and optic, because of genetic peculiarities, any of the cranial nerves may be the seat of neurofibromata.

In general, the sensory nerves are more susceptible and the acoustic pre-eminently so. Primary tumors of the cerebellum or brain stem will often, at some stage of the disease, simulate closely the syndrome in question. Indeed, many of the cases of this type are recorded in literature as cerebellar tumors, pontine tumors, etc.

From a differential diagnostic standpoint, particular stress was laid on the appearance of cranial nerve symptoms before the development of symptoms of intracranial pressure. Tinnitus, progressive deafness, facial tics, neuralgias and other symptoms referable to the fifth nerve, were mentioned as instances in point.

Dr. MILLS said he had several similar cases. In two or three instances he had seen operations done for tumors in this locality which were unsuccessful. He thought it was possible to have a growth of a different nature from that described, though the symptoms might be very similar. A very important feature was that the early symptoms were neural.

Dr. SACHS agreed with Dr. Mills and referred to a case of sarcoma of the cerebellum in the ponto-cerebellar angle that he reported several years ago. In tumors occurring in this region, most of the symptoms are unquestionably due to pressure upon the cerebellum. He considered the operation for the removal of growths located in this special angle a very serious one. The angle is barely accessible without serious impairment of important function.

Dr. LANGDON spoke of a case bearing on the question of diagnosis between neurofibroma and sarcoma. Deafness was the only prominent symptom for several years. The subsequent history indicated a slowly developing growth occupying the medullo-ponto-cerebellar angle. There was complete deafness with slight facial sensory and motor symptoms. A year before death, fourth, fifth, and sixth nerve symptoms were well developed. At the autopsy eight small tumors were found, some in the pia, but most of them in the dura. He thought the long duration of the symptoms (seven years) might furnish a point in the differential diagnosis between a sarcomatous growth and neurofibromatosis.

Dr. PATRICK said it was extremely difficult to determine the nature of the growth from the symptoms.

**Progressively Developing Hemiplegia, Later Becoming Triplegia.**—This was the report of a case by Drs. CHARLES K. MILLS and WILLIAM G. SPILLER of Philadelphia. Hemiplegia is gradually developed on the right side, the lower extremity being more markedly and probably earlier affected than the upper, the case therefore belonging to the clinical type of unilateral progressive ascending paralysis. After several years the left lower extremity also became paralyzed, but not to the same extent as the right. The reflexes were all markedly exaggerated, the Babinski response being present. Sensory symptoms were absent. Microscopical examination showed intense and long-standing degeneration of the right crossed and the left direct pyramidal tracts, the degeneration extending into the pons but not into the left cerebral peduncle; also comparatively recent degeneration of the left crossed and the right direct pyramidal tracts traced by the method of Marchi into the lower part of the right internal capsule. No lesions, degenerative or focal, were found elsewhere; the case therefore was one of uncomplicated primary degeneration of the motor tracts, much greater and older in the right crossed and left direct pyramidal tracts. The case was regarded as a corroboration of the clinical type described by Mills in the *Journal of Nervous and Mental Disease*, April, 1900.

**Chronic Progressive Hemiplegia.**—Dr. HUGH T. PATRICK of Chicago reported the case of a girl eighteen years of age, who had been perfectly well and normal in every way until her fourteenth year, when the right hand and foot began to grow clumsy and weak. This disability had gradually increased until the present time. The entire right side is now paretic, with distinct diminution of muscular volume but no localized atrophy. Although the general appearance and action of the involved extremities suggested flaccidity, the deep reflexes were all greatly exaggerated and Babinski's sign well marked. It seemed easy to exclude all well-known diseases, but he was inclined to think that the case might belong to a new clinical type recently described by Mills under the name "Ascending unilateral paralysis." Concerning this type, however, he had occasion to examine repeatedly one of the two cases published by Mills, and was satisfied that the case was an example not of a new disease, but of unilateral paralysis agitans. This patient would be presented to the association later, and the symptoms of paralysis agitans demonstrated. Two additional cases of one-sided paralysis agitans without tremor were briefly reported.

**Progressively Developing Hemiplegia.**—This was the report of a case and exhibition of the brain by Dr. G. M. HAMMOND of New York. The patient gradually developed hemiplegia on the right side, beginning in the leg, extending to the arm, and finally affecting the face, taking four months for the total extension of the paralysis. Later, paralysis began in the left leg and finally embraced the left arm but not the face. The autopsy disclosed extensive degeneration in the white matter of both hemispheres, more extensive on the left side. This could be traced downward in both motor tracts.

The last three papers were discussed together.

Dr. H. M. THOMAS of Baltimore referred to a case recently under observation of a boy in whom there was marked mental change. The autopsy showed degeneration of both pyramidal tracts without any observable lesion.

Dr. W. HIRSCH of New York spoke of two patients with progressive hemiplegia, in whom distinct mental symptoms of general paresis developed at the end of two years. Secondary degeneration of the pyramidal tracts in paretics is well known.

Dr. STARR, in discussing Dr. Mills' paper, cited the case of a woman presenting at first the symptoms of spastic paralysis in the right leg. Gradually the right arm became involved, but the face escaped. The only diagnosis possible was unilateral sclerosis. About a year later the left side was similarly affected, in addition to atrophy in the muscles of the arm and leg. Soon after, bulbar symptoms developed rapidly, and death took

place eighteen months after the onset, with all the signs of well-marked amyotrophic lateral sclerosis. It seemed to him that, in Dr. Mills' case, the differential diagnosis of amyotrophic lateral sclerosis should not be overlooked. He thought these cases should be classified into a large general group exclusively limited to the motor tract of the nervous system.

Dr. DANA spoke of a case which seemed to belong to the type described by Dr. Mills. The condition appeared somewhat like a unilateral type of multiple sclerosis. A man forty-five years of age gradually developed descending right hemiplegia associated with the usual accompaniments of spasticity. The diagnosis rested between a sclerotic area in one cerebral hemisphere, or some type of paralysis agitans. A man with unilateral paralysis agitans without tremor, at present under observation, at first impressed him as being a case of hemiplegia due to some degeneration of the motor tract. Subsequently he developed the characteristic symptoms of paralysis agitans.

Dr. COLLINS reported the case of a man who became gradually hemiplegic on the left side. About a year later he began to have emotional symptoms, such as involuntary laughter without adequate cause. Subsequently a right hemiplegia developed. The emotional symptoms are now conspicuous, and he thought the lesion therefore involved the thalamus.

Dr. SACHS had seen a patient with progressive hemiplegia who gradually became completely paralyzed and demented, and finally succumbed to the disease.

Dr. PATRICK then showed a patient (the one referred to in his paper) with unilateral paralysis agitans without tremor, in whom the condition had existed for five years. Tremor could be developed in the affected upper extremity when the patient made an effort forcibly to grasp an object with the opposite hand.

Dr. MILLS admitted that there were several things in Dr. Patrick's case which pointed toward the diagnosis of unilateral paralysis agitans, but he did not feel thoroughly convinced that this is the correct diagnosis. He said that in his original paper he had stated that among the affections from which it was to be differentiated was unilateral amytrophic sclerosis. The patient was under obsevation from 1897 to 1903. The only systemic disease found on microscopical examination was the pyramidal degeneration described by Dr. Spiller. He considered the case referred to by Dr. Collins as one of disseminated sclerosis with bulbar symptoms. He thought the discussion had shown the disease to be much more common than was supposed.

Dr. HAMMOND said that his case showed a different type of disease from the one described by Drs. Mills and Spiller. He thought it would take more than a close observer to tell the difference at the bed-side before a post-mortem examination has been made.

**Flaccid Paralysis Following Cerebrospinal Meningitis.**—Dr. WM. N. PULLARD of Boston read a paper with this title and stated that the ordinary forms of paralysis following cerebrospinal meningitis as described in the textbooks are spastic. There is, however, also a flaccid form which usually appears as paraplegia. This closely resembles in its later stages the conditions which are found in the later stages of anterior poliomyelitis. In the earlier stages it is characterized by the persistence of pain and tenderness to a much greater degree than occurs in poliomyelitis, and also by a tendency to accompanying spastic contracture. He thought it very probable that some of the epidemics which have been described as anterior poliomyelitis were really due to cerebrospinal meningitis, the existence of which in the epidemic form is not uncommon, while the evidence for the existence of true epidemics of anterior poliomyelitis, usually a sporadic affection, is not yet absolute. Several cases of this form of paralysis were reported.

Dr. J. J. THOMAS of Boston had seen many of these cases. He thought they were cases of cerebrospinal meningitis. During the acute stage of poliomyelitis it was often difficult to make a diagnosis. He had also noted the presence of tenderness, the early formation of contractures, and the tendency of the paralysis to be bilateral.

Dr. HENRY UPSON of Cleveland referred to a case of spinal meningitis with multiple neuritis which he reported several years ago. There was diffuse tenderness over the legs. The autopsy revealed both conditions in a marked degree.

Dr. KNAPP thought the previous history would enable us to make a distinction between cerebrospinal meningitis and anterior poliomyelitis. In cerebrospinal meningitis the symptoms might be so slight and so little characteristic as to be easily mistaken for the initial fever and malaise of anterior poliomyelitis.

Dr. J. J. PUTNAM doubted whether it was always possible to make a differential diagnosis or to decide that cerebrospinal meningitis is present. He thought it important to limit the differentiation, and to recognize the two types, but it should be noted that the two stood in a certain sort of relationship to each other. He believed what was ordinarily called anterior poliomyelitis occurs in epidemics. He referred to twenty-eight cases occurring in the vicinity of Boston and seen by him.

Dr. E. D. FISHER of New York said there was no difficulty in making a differential diagnosis between cerebrospinal meningitis and poliomyelitis, except during an epidemic, when both conditions were found.

Dr. PATRICK thought the examination of the cerebrospinal fluid was of value in making the diagnosis.

**A Case of Alexia.**—Dr. PHILIP ZENNER of Cincinnati reported the case of a man sixty-three years of age. Forty years ago he had a venereal sore, but without any constitutional manifestations. Eighteen years ago he had an acute articular rheumatism. For several years he has had some dyspnœa on exertion. The alexia came on in April, 1902, during an attack of dyspnœa. It is not improbable that the attack came on during sleep. The only other speech disturbance which he had observed is occasional difficulty of finding a word, or using a wrong word. In addition to the aphasic manifestations and occasional dyspnœa, he complained of irregular heart action, precordial pain, and disturbed sleep. The heart was enlarged and the sounds muffled. The urine contained some albumin but was otherwise normal. There was not motor paralysis nor ataxia. The cutaneous sensations, hearing, taste, and smell, pupils, optic disks, and knee-jerks were normal. The ankle-jerks were absent. There is a right hemianopsia in each eye. Central vision is normal. He often repeats himself in conversation, forgets occurrences of the day, and vacillates in his actions. But in general, he manages his business and his own affairs. He fully understands everything said to him, and expresses himself clearly and fluently. He is altogether unable to read. But he can tell single letters, though not always with ease, and often incorrectly. He recognizes capital letters much better than small letters. He can read only so far as he is able to spell the words. Whenever he succeeds in spelling the word correctly he recognizes it at once. During the time he was under observation there was no change in his condition. As to the seat of the lesion, the hemianopsia pointed clearly to the occipital lobe. The relation of the angular gyrus, now generally accepted as the visual speech center, to the lesion can be less definitely outlined. Its destruction would, doubtless, cause more extensive aphasic manifestations than existed in this case. The lesion probably enroaches upon this area and severs its relations with the lower visual centers.

Dr. SMITH BAKER of Utica said there was a very easy fatigue of accommodation in such cases, and that might possibly give a clue to the difficulty experienced by the

patient in recognizing certain figures which differ in form from certain other figures.

Dr. LANGDON believed that the lesion was distinctly limited to a visual type of aphasia. He referred to a case of pure alexia he had seen, in which the man was unable to read after a few moments what he had written.

Dr. KNAPP mentioned the case of an active intelligent woman of middle age who awoke one morning with considerable dizziness. A valvular lesion of the heart was present. There was well-marked alexia with right hemiplegia, and slowness in recognizing objects by sight, although the visual fields were normal. She was able to write. She recognized her room and household perfectly well, and also the neighborhood in which she had lived for many years, but everything seemed reversed. The house seemed to be on the opposite of the street, and the relations of the house seemed exactly reversed.

**The Principles Underlying Practice in Mental Therapeutics and Legal Regulations of Its Practice.**—This was the title of a paper by Dr. RICHARD DEWEY of Wauwatosa. He concluded that the practice of mental therapeutics is an important part of the practice of medicine as a whole, and should be taught systematically and so regulated as to prevent fraudulent practices or imposition.

Dr. BAKER believed that the time is coming when we shall be forced to give more attention to the mental side of the human constitution in our attempt to restore people to health. He thought such method should play an important part in all the sources of what we now call purely nervous affections, because upon last analysis they prove to be neuro-psychical.

Dr. ZENNER said there was nothing of more value than psychic treatment, and that such treatment often produces transitory relief of organic disease. In a great many therapeutic measures the relief comes through the mind.

Dr. LANGDON did not think it possible to approach a solution of the problem until we have a better curriculum in the medical schools.

---

THIRD DAY, THURSDAY, MAY 14.

**The Neurasthenic Neuralgias.**—This was the title of a paper by Dr. FRANK K. HALLOCK of Cromwell and was based on a study of forty-five cases, with the following conclusions: Clinically two varieties exist: One is non-objective, the pain existing with very slight, or no concomitant physical symptoms; the other is objective, the pain being accompanied by localized symptoms, sensory, motor, vasomotor, secretory, trophic. The non-objective neuralgias may be sub-divided into a paræsthesic type (distinct from the paræsthesic of hysteria, etc.), a spontaneous form with or without an appreciable cause, and a habit form due to an antecedent neuritis. The term neurasthenic should, perhaps, be limited to the neuralgias which are non-objective, that is, without marked concomitant physical signs. It is often very difficult to distinguish between a neuritis of the sensory nerves and a neuralgia with pronounced local symptoms. The motor disturbance, direct or indirect, is generally more marked in genuine neuritis. Another diagnostic point is the fact that decided variations in the general physical state, as well as psychical influences, produce fluctuations in the pain relatively greater in neuralgia than in neuritis. The pathology of neurasthenic neuralgia is necessarily obscure. The extent to which excitability of the sensory nerves is of central or peripheral origin is hard to determine. Cases with marked local symptoms can best be explained by the supposition of a mild grade of perineuritis rather than a neuritis, interstitial or parenchymatous. The pathology of the non-objective neuralgias, if it is to be interpreted peripherally and not centrally, is most likely of the nature of chemical stimuli due to localized nutritional and metabolic defects. The neuralgia being considered merely a symptom, the prognosis depends chiefly upon the general physical rallying power plus the type of individual. The treatment consists largely in the regulation of the patient's life, and attending to the underlying neurasthenic state. In the management of the local condition the first requisite is rest, partial or complete, according to the severity of the attack. Later, localized applications of massage, hydrotherapy, electricity, dry hot air, etc., are of varying utility in different cases. Inasmuch as the neuralgia is apt to be obstinate and of prolonged duration, it is advisable to teach the patient how to bear pain in the most philosophic manner. Hypnotic suggestion is of great value in certain cases.

Dr. BAKER had been accustomed to look upon these cases, especially the non-objective variety of neurasthenic neuralgia, as being best explained in a general way by nerve starvation and by adding to that the newer concept of nerve poison.

Dr. LANGDON considered the differential diagnosis in cases of neurasthenic neuralgia as of very great importance. In his experience, any sensation that can be called a true neuralgia is a comparatively rare symptom in neurasthenia. Pain, and even tenderness of the nerve trunks often occur in neurasthenia, but such cases belonged to the paræsthesias, and some other cause than neurasthenia should be looked for.

Dr. LEONARD WEBER of New York believed it necessary in every case of chronic neuralgia to investigate as to previous syphilitic infection. In his opinion, no disease was more likely to be associated with neurasthenia in the course of years than old syphilis, in which neurasthenic neuralgias might occur. As a rule, surgical intervention is not followed by good results.

Dr. ANGELL thought it very easy for nervous patients to exaggerate unintentionally the significance of symptoms, especially regarding pain. He agreed with Dr. LANGDON that many pain cases are cases of paræsthesia.

**Modern Theories of the Emotions and Their Bearing on Mental Derangements.**—This was the title of a paper by Dr. HENRY UPSON of Cleveland. He concluded that in different forms of sensation the emotional element varies. The special senses and tactile sensibility set up intellectual mental conditions. The pain sense and visceral sensibility have a slight localizing value and an emotional content that varies from moderate pleasure or discomfort, to the more marked and definite emotional states; either of these elements may be present without the other, especially in the case of visceral sensibility, which often fills the emotional field of consciousness without percepts of localizing value. The modern view of the emotions as perceptions of altered visceral conditions, at some times due to psychic causes, at others dependent on physical disease of the viscera, functional or organic, is derived in part from medical observations and in turn illumines the field of psychiatry. The viscera constitute the instrument played upon by psychic stimuli, and the brain centers are receiving stations for resulting sensations, present in consciousness as emotions. Certain relations between disease and resulting emotions were briefly considered.

Dr. H. T. PERSHING of Denver had recently given attention to this subject with special reference to the treatment of emotional disturbances in neurasthenia and hysteria. It was obvious that the first thing to do is to remove the idea exciting an undesirable emotion. In many cases, he found great advantage in teaching the patient to suppress voluntarily the motor reaction peculiar to the depressed emotion, and to imitate voluntarily the reaction of the opposite emotion. He thought many emotional disturbances were due to physical causes.

Dr. KNAPP said that in patients who have exhausted themselves in struggling against an insistent idea, it was better to suggest to them to let the whole thing go, and to endeavor to divert the patient's attention, and let the idea come on unrestrained.

Dr. BAKER thought it should be a matter of routine to inquire whether the patient has been subjected to shock

within recent months, or whether he is under prolonged intense emotional excitement of any kind. The result of the latter condition is direct interference with nutrition.

Dr. EDWARD B. ANGELL of Rochester said it was much wiser to get at the obstruction indirectly rather than directly, as it was impossible to argue with a person's morbid notion without emphasizing it.

**Paralysis Agitans Complicated with Delusional Mania.**—This was the report of a case by Dr. JOHN PUNTON of Kansas City. A man sixty-one years of age with good family history was well until four years ago, when he suffered from an attack of the grippe, from which he recovered a few weeks later. About two years ago he gradually became very nervous, and there was marked muscular rigidity and a fine tremor. He also assumed the attitude and gait common to paralysis agitans, together with the characteristics facies. These symptoms, together with vasomotor disturbances, continued to develop and grow worse in spite of treatment, which caused him to become quite despondent, and later he presented all the symptoms of true melancholia. Subsequently, there was acute mania with mental exaltation, delusions, and hallucinations. In April, 1901, he was admitted to the hospital with the typical picture of paralysis agitans, complicated with delusional mania. At the end of eighteen weeks he recovered his mental health, but the paralysis agitans had not improved.

**General Paralysis with Focal Symptoms and Atrophy.**—This was the report of a case of Dr. ADOLPH MEYER of New York. In a man forty-two years of age, difficulty in the use of the left arm developed slowly, together with inefficiency in work, which finally passed into slight expansiveness, characteristic for general paralysis. Under observation, the difficulty was found to be an anæsthesia of the left arm of central origin, leading to deficient use when the eyes are closed, occasional slow twitchings of the left arm, and the gradual development of rigidity and spreading of the sensory and motor symptoms over the whole left side; also production of left hemianopsia and increasing dementia. The diagnosis of a typical general paralysis was corroborated by the autopsy, which showed atrophy of especially the posterior part of the right hemisphere without focal lesion, but marked narrowing of the cortex and distension of the ventricles, and contralateral gliosis of the whole left part of the cerebellum, with partial degeneration of the cortex; the histological process was typically that of general paralysis, which was much less marked in the left hemisphere. There was a probability of syphilitic infection nineteen years before the onset. Technically, the case showed the decided advantages of injection of the brain, with 10 per cent. formalin before removal at the autopsy.

**General Paralysis with Focal Symptoms.**—Dr. A. HOCH of Waverly reported two cases: Case 1, In the course of a year at first repeated convulsive seizures; later, attacks of twitching on the right side. Then sudden aphasia with palsy of the right side. Under observation euphoria and general dulness; motor aphasia, paresis, and ataxia of right arm, with frequent twitching. Later, involvement of whole right side. Death in convulsions. Autopsy: lesions of general paralysis with much greater involvement of left side; the left hemisphere weighed 112 grams less than the right. Case 2, Complained of headaches, stupid feeling, and in ability to express himself; at times irritable. A year later, apoplectiform attack. Following this, persistent paraphasia with difficulty to understand written and spoken language. Appreciation of defect. Hemianopsia. Argyll-Robertson pupil on the right side. General euphoria and irritability. Death in convulsions. Autopsy revealed the usual lesions of general paralysis with more pronounced changes in the left hemisphere, which weighed 120 grams less than the right side.

The last two papers were discussed together.

Dr. BULLARD asked Dr. Meyer whether he had found astereognosis or not. He said it was unusual to find cerebellar trouble in cases in which the hemisphere of the opposite side is affected. In the reports of autopsies of feeble-minded this seems to be the ordinary occurrence (in which one hemisphere is more especially affected) to have the opposite cerebellar hemispher e likwise affected.

Dr. MEYER replied that he did not speak of astereognosis on account of the presence of anæsthesia. He was inclined to utilize the case in corroboration of his view that the anterior central convolution is the essential motor region, plus, of course, some immediate sensory activity, but that the parts behind the Rolandic fissure are essentially reception stations, also of influence in the work.

**Double Optic Neuritis Without Assignable Cause.**—Dr. HOWELL PERSHING of Denver reported a case of this character, in which the course was acute, and when the neuritis began to subside, it subsided rapidly in one eye while it advanced in the other. The patient was, otherwise, in perfect mental and physical health.

Dr. PATRICK had seen a case of typical choked disk, due to simple chlorosis, the patient making a complete recovery under treatment for the chlorosis.

Dr. H. K. MITCHELL of Philadelphia mentioned the case of a girl seventeen years of age who made a perfect recovery from a pronounced double optic neuritis with apparent meningeal symptoms.

Dr. BULLARD expressed the opinion that in many of these cases there might be a certain amount of hydrocephalus.

**Development of the Neuro-fibrils in the Nerve Cell.**—Dr. STEWART PATON of Baltimore exhibited microscopical specimens illustrating the development of the neurofibrils in the nerve cells. He explained that they make their appearance in the nerve cell of the embryo, first in the apical processes, and about the time of birth, can be stained in the cell bodies in the larger cells of the cerebral cortex. They develop later than do the Nissl bodies. He also demonstrated their degeneration in pathological processes.

Dr. TAYLOR said that the work of Dr. Paton was new in this country. He thought it a matter of very great importance as to whether we can attribute any definite significance to the alteration found in the neuro-fibrils.

**Election of Officers.**—The following named gentlemen were elected for the ensuing year: *President*, Dr. Frank R. Fry of St. Louis; *Vice-Presidents*, Dr. Hugh T. Patrick of Chicago and Dr. William G. Spiller of Philadelphia; *Council*, Dr. Charles L. Dana of New York and Dr. J. J. Putnam of Boston; *Secretary and Treasurer*, Dr. G. M. Hammond of New York.

---

**The Dangers of an Exclusive Milk Diet in Nephritis.**—Alfred C. Croftan discusses, first, the effect of an exclusive milk diet on general nutrition. Theoretically, full nutrition can be maintained on an exclusive milk diet. But in order to do this enormous quantities of milk must be consumed, and even then there is a deficiency of one all-important element, iron. Aside from overloading the stomach and flooding the circulation with enormous quantities of water, we force the patient to assimilate and disassimilate nearly twice as much albumin as he is accustomed to and as he requires. As far as the renal epithelia are concerned, much water, much urea, and much phosphate, all elements that are carried to the kidneys in large quantities when we feed our nephritics on an exclusive milk diet, act as irritants to the renal epithelia, and one consequently harmful. The ingestion of large amounts of water mechanically does injury to the stomach, the heart, and arteries. The writer does not think that we are at present able to formulate any fixed rules in regard to the feeding of nephritics. He thinks that the consensus of clinical experience speaks for more liberal feeding of kidney cases than is usually adopted, and decidedly against one-sided alimentation. It speaks by all means against an exclusive milk diet.—*Medicine.*

## A CIRRHOSIS BRUSH.

By ROBERT T. MORRIS, M.D.,
NEW YORK.

In our operations for making venous anastomosis in cases of cirrhosis of the liver, rapidity of work is a matter of consequence to the patient.

Scarification of the peritoneum, or removal of the endothelial layer at chosen sites by scrubbing as recommended by Talma, Morrison, and others, consumes more time than should be given to the work.

The brush here pictured allows one to be very expeditious in removing endothelium. The brush is nine inches in length, and has a curve of handle and of bristle surface which will allow one to reach readily the posterior border of the liver and the corresponding surface of the diaphragm. It is a five-row brush, with the stiffest unbleached bristles, varying in length from one-fourth inch at the tip to six-tenths of an inch at the summit of the convexity. When the brush is boiled in advance of an operation, the bristles soften to a degree which seems to be most useful, but if one prefers, the brush can be sterilized in formalin solution, which leaves the bristles very firm and hard. With this brush a few strokes suffice to remove the endothelium from the omentum spread out over the hand, and from the corresponding parietal peritoneum of the anterior abdominal wall. If the liver is then depressed with one hand, its cephalad surface and the concave surface of the diaphragm can be so quickly prepared for venous anastomosis that the entire operation from the time of opening the abdomen to the closing of the incision can be done in ten minutes. The work can be done through a much shorter incision than is required for some of the other methods. My views on the subject of short incisions in surgical work are generally misquoted. The tendency with most beginners in surgical work is to make too short incisions, and this leads to haggling work, and to delay in accomplishing the object of the operation. With the establishment of confidence in one's resources, the tendency is to make bolder and freer incisions, and to adopt that plan as a fixed custom without realizing that acquired expertness will allow one to go back to incisions so short that the patient is given the advantage of the mildest possible attack of incision. It is my belief that in abdominal surgery, particularly, short incisions indicate lack of skill on the part of the beginner, and that they are a test of skill, or at least a legitimate end of skill for one who has become expert out of successful experience.

In cases of cirrhosis of the liver, a long incision and a wound kept open for long time are factors inviting septic disaster, because the peritoneal lymphatics are so disordered in function that they cannot give ordinary protection.

58 WEST FIFTY-SIXTH STREET.

**Lepers in the Danish West Indian Islands.**—Dr. Ehlers, an emissary of the Danish Government, has found 102 lepers on the islands of St. Thomas, St. Croix, and St. Jean. He thinks the disease is of a mild, curable character. There are no good leper hospitals.

### SOME CASES TREATED BY THE *X*-RAY.

FACIAL CANCER, CARBUNCLE, CHELOID, ACNE, ALOPECIA AREATA, SYCHOSIS, FIBROID TUMOR, PSORIASIS, AND LUPUS.

BY WILLIAM JAMES MORTON, M.D.,
NEW YORK.

CASE I.—Carcinoma of the left orbital region; inoperable. George Van A., aged sixty-three years, Jamesburg, N. Y. June 24, 1902. (See Figs. 1 and 2.) The disease began about fifteen years ago as an apparent mole on the cheek, below the lower canthus of the left eye. During ten years this mole-like growth laid fairly dormant, and then broke down into an ulcer with the formation of scabs. The ulcer increased in size until two years ago it was about one-half an inch in diameter and quite deep. It was now treated by a cancer paste, and apparently healed in about a month. But soon hard nodules formed around the edges and quickly broke down into an excavation larger than ever before, and discharged much pus. The bone of the orbit now became involved. In November, 1902, the paste was again applied, but the disease still continued to spread angrily in every direction.

He then took the Alexander treatment of about thirty-seven injections, but with no benefit; on the contrary, the disease has spread rapidly until it presents the appearance shown in the accompanying illustration. (Fig. 1.)

Present appearance: Both the upper and lower eyelids are more than half destroyed, both presenting at the junction of the diseased with the normal tissue a raised and indurated edge. The orbital socket presents a deep excavation; the raised and indurated edges of the ulcer extend outwardly beyond the orbital ridge, forming altogether an ulcer about one and one-half inches in diameter. Beyond the ulcer, extending on to the temple outwardly, is a mass of hard nodulated tissue about two inches in area, and feeling as if it were bone. The ulcer has an angry appearance, and discharges pus freely.

Since the patient had already lost the sight of the right eye by an accident, he was extremely anxious about a possible injury to the sight of the sound eye, and his anxiety led to a mild and discreet use of the *x*-ray.

Treatments were begun June 4, and continued three times weekly until August 22; time of exposure, fifteen minutes; distance of ulcer from target, nine inches; medium strength *x*-ray from a hard tube, showing plainly in the fluoroscope double bones at the wrist at a distance of two feet; a lead mask as usual; fifteen inch Ruhmkorff coil, mercury jet interrupter. In twenty days the nodules were visibly diminished in size and the ulcer was evidently almost healed (Fig. 2), and treatment might have stopped at this time except for the anxiety of the patient to make sure of a cure. In all, thirty-two treatments were given, extending over a period of eighty days.

It is interesting to note that this ulceration has not, apparently, healed by the usual process of cicatrization, for there exists not the slightest trace of contraction. The upper eyelid presents now a normal appearance, and the lower is new skin, but not scar tissue.

On January 31 the patient returned for precautionary treatment of a small point about the size of the head of a pin, and a photograph taken to-day would present even a better appearance than the one here reproduced.

CASE II.—July 2, 1902. Wm. L., aged fifty-two years, Astoria, L. I. Cutaneous carcinoma on both cheeks. Patient referred by Dr. Walter Eyre Lambert. Disease began one and one-half years ago as a small pimple on the right cheek just below the eye. Scabs formed and dropped off frequently. Soon an ulcer formed about one inch in diameter.

Treatment began July 2 and continued three times weekly up to thirteen treatments. About the eighth treatment, the ulcer showed signs of healing; it grew smaller and smaller, and ceased to form scabs and was perfectly healed in five weeks.

About one year ago a similar growth appeared on the left cheek one-half inch below the left eye. The growth was at first a round and hard lump the size of a pea. Six treatments, three times weekly, caused the ulcer to heal entirely.

Patient again examined October 17, and the skin appears to be sound. There is no sign of cicatricial tissue and no scar, nor can the site of the ulcers be found by examination.

CASE III.—October 10, 1903. M. W., aged eighty years. Epithelioma of nose. (See Figs. 3 and 4.) Existent since two years. Treated constantly by experts and no progress toward cure made. The ulcer is a deep hole with irregular, indurated, and rounded edges surrounded by a reddish areola. A scab forms continuously over the ulcer. The entire bridge of the nose is involved and a perforation of the bone and an opening into the inside of the nose has occurred.

The swelling, redness, and scab disappeared after twelve treatments, say at the end of six weeks. At the end of three months (with altogether twenty-four treatments) the epithelioma appears to be completely cured.

A perforation of small caliber from the outside to the inside of the nose remains as a result of tissue already destroyed by the cancer. The imperfections of the photograph of Figure 3 are largely due to senile tremor.

CASE IV.—April 25, 1902. B. H., aged sixty-two years. Epithelioma of lower lip. Referred by Dr. Am Ende.

Disease began fourteen years ago on the under lip as a hard, defined area. At the time of beginning treatment, the lip presented a most grievous and "ugly" appearance. The disease had invaded the entire length of the lower lip, precluding any reasonable operation by the knife. Roughly speaking, the lip looked to be very much swollen and projected forward. It was of a dark purplish

color and intensely hard to the touch. Inside the lip and involving the mucous membrane there existed a firm and indurated horizontal ridge, painful to examination and constituting an inside border to the cancer. Patient suffered much pain.

Treatment: *X*-ray, shield for upper lip and face.

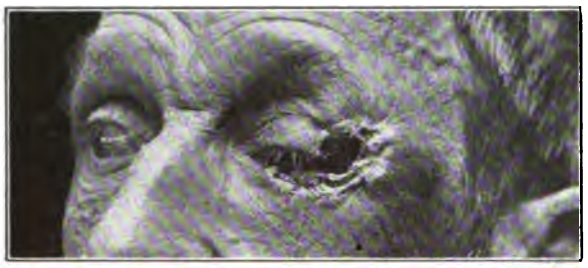

FIG. 1, CASE 1.

May 2: Complete relief from pain for twelve hours.

May 7: Scab from central and hardest portion of tumor fell off.

May 26: Now no pain at all. Hair of beard where exposed to *x*-ray has fallen out.

June 13: Cancer entirely disappeared—no symptoms and no indications of disease can be discovered.

Duration of treatments about seven weeks and about twenty-one treatments.

It should be stated in connection with this case that Dr. Am Ende during the *x*-ray treatment maintained for his patient a dosage of thyroid extract manufactured especially by himself, in order to be sure of its quality, and full weight in securing the excellent result should be given to the medicinal remedy. Up to the time of treatment by the *x*-ray, however, the thyroid by itself had produced no effect, although its use had been for a long time continued.

CASE V.—October 6, 1902. Mrs. G., aged thirty-seven years. Epithelioma of lower eyelid. (See Figs. 5 and 6.)

Twelve years ago injured the lower eyelid; four years ago the injured spot began to itch and a scab appeared, forming altogether a small ulcer with an indurated base and elevated and rounded margins. The tumor has been cut out once, once scraped out and various ointments and nitrate of silver have been used, but it refuses to heal and is now enlarging.

Patient reports that specimens examined by Dr. I. Danforth of Chicago and by Dr. Ard of Plainfield, N. J., have been pronounced to be epithelioma.

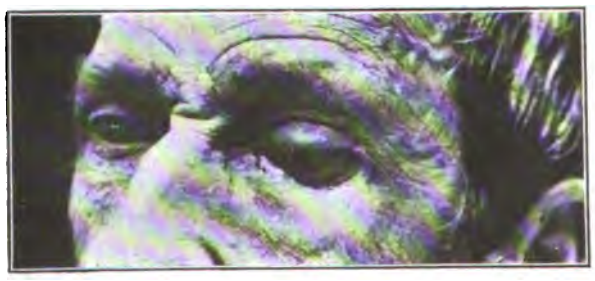

FIG. 2, CASE 1.

December 27: In about eighty days, or with about thirty-three treatments, the ulcer appears to be cured. (See cut.) Incidental to the disappearance of the ulcer is the appearance of a notch in the lower lid showing where previous operations had taken place. The new growth had previously filled up this notch.

In this case I frequently employed adrenalin 1-1,000 sol., one drop, to produce a primary ischæmia of the ulcer before *x*-radiation. As is well known, the blood offers, by reason of its density, some obstruction to the penetration of the *x*-rays, and it is quite possible, by securing an artificial pallor, to increase the effect of the treatment. I pursue the same plan frequently with other cases.

The patient now went to Europe with the understanding that she report progress on her return this spring.

Bearing in mind the case reported by Dr. Wilbur B. Marple of this city, of favorable effects due to adrenalin alone in such a case, I had thought of advising her to use this remedy while abroad, but a week's preliminary trial satisfied me that the secondary reaction more than counteracted any advantage gained from the primary pallor. I therefore am satisfied to use adrenalin merely as a mechanical producer of pallor preliminary to *x*-ray treatment and not for an otherwise curative purpose.

CASE VI.—April 4, 1902. H. W., aged forty-four years. Epithelioma of face, on cheek below the eye. First noticed a small red speck like a "broken vein" about fifteen years ago. About five years ago this spot became sore and increased in size and began to form scabs which from time to time fell off. The ulcer now measured about one inch in diameter, while the disease also extends beneath the adjacent apparently sound skin. Patient has tried caustics

FIG 3, CASE 3.

and various measures of treatment with no avail and is much discouraged.

Treatment: *X*-ray with shield.

May 23: Ulcer began to heal at once but slowly. Measurement to-day, one-half by one-half inch in diameter.

June 24: A very thin, delicate, new skin entirely covers the ulcer. This skin looks as if it might break down at any moment and causes doubt as to the results for a while yet. Referred to Dr. L. Duncan Bulkley, who writes, "There seems to be no doubt about there having been an epithelioma, but now there are almost no elements for a diagnosis. The *x*-rays have certainly done excellent work."

The case had been really cured in seven weeks with twenty-one treatments. In July, however, a very small persistent hard spot, perhaps double the size of a pin head, caused him anxiety and I gave a number more of treatments and the patient returned to Canada.

On October 17 he writes that the cure seems to be permanent, and this is corroborated on February 1, 1903.

Dermatitis was freqeuntly established. The healing is not like cicatricial tissue, but is true skin, which is indistinguishable from the adjoining skin.

CASE VII.—Miss S., epithelioma of the face, has been quite fully reported in the issue of this journal of March 8, 1902, as Case VII. It is presented here, together with an illustration, Fig. 8, as an offset to

any too favorable impression created by anything in this paper in regard to cancer of the face. The patient made, as reported, steady progress for a few months; the edges inverted, the indurations softened, the ulcer steadily decreased in size and a peninsula of healthy skin projected some distance toward the center of the ulcer. Then there steadily and slowly developed an extensive spread of the disease which no effort on my part with the *x*-ray or the violet ray could stem, and I was obliged to admit defeat. I saw but one hope remaining for her, and sent her, also with the advice and consent of Dr. Clement Cleveland, who had originally sent her to me, to Dr. A. R. Robinson, for an attempt to curtail and cure the ravaging ulcer by means of caustics. I understand that the unfortunate patient is now making favorable progress under the caustic treatment. I have no explanation to offer of this failure, except that others like myself have found this type of deep-seated epitheliomata with everted edges and "pearly nests" to be difficult if not impossible to cure with the *x*-ray. In all fairness it may be stated that doubts of the disease being an epithelioma were expressed by good authorities, but Dr. Robinson, on the other hand, whose opinion

Fig. 4, Case 3.

carries great weight, believes it to be unmistakably a true epithelioma.

Case VIII.—Carbuncle. April 13, 1902. The patient was brought to me by Dr. J. M. Liebermann, who has kindly furnished me with the data relating to the onset and final outcome of the case.

Thomas P. D., lawyer by profession, forty-four years of age, appearance of good health. Had a carbuncle a year ago. Had to stay in bed for two weeks in succession, suffering intense pain awaiting the softening of the tissues; duration of attack altogether between six and eight weeks. Two ugly scars now on the back of the neck attest the severity of the case. The patient was first seen by Dr. Liebermann on the 11th day of April; he had been suffering intense pain then for three of four days, with high temperature; a new and large carbuncle had developed on the back of the neck. The pain extended down the neck to the left scapula and induration extended to the occipital protuberance as well as downward over a large area.

Application of *x*-rays, a "high tube," powerful *x*-ray, six inches distance, hole generously large cut in a sheet of lead for a shield, duration eight minutes.

Within two minutes the immediate carbuncle area turned violent red, then purplish red and dusky in hue; this hue was maintained to the end of the treatment of eight minutes, when, upon examination by palpation, it was found that what had a few minutes before been a hard, stony tumor had now

Fig. 5, Case 5.

broken down into a softened mass three-quarters of an inch in diameter, leaving still, however, a crater-like ring of moderate induration round it; the *x*-ray had self-evidently forced a resolution in this brief space of time. At the same time the patient was completely relieved of pain and could with the greatest freedom turn his head from side to side. This in marked contrast to the fixedness of the pose of his head when beginning treatment.

Second treatment, April 14, with precisely the above effects over a wider area.

Third treatment, April 16. This treatment was really unnecessary, for the carbuncle was evidently so "ripe" that a slight touch of a knife to the very thin layer of skin over it would have permitted of an escape of its contents.

On the night of April 16 the carbuncle burst spontaneously, and on the next day in cleansing the wound no pus, except a mass of cheesy matter, was removed, and by slightly pressing on the border of the wound, the root of the carbuncle was removed in the shape of tenacious tape-like matter of two and one-half inches in length and about one-eighth inch in width.

Neither during the closing of the wound, nor at any time during the attendance, was pain experienced by the patient.

Fig. 6, Case 5.

Full recovery of the wound occurred on April 22, when the patient was discharged, making altogether eleven days for treatment of this most ugly carbuncle.

Patient during all the time was able to attend to his usual occupation in court and in office without inconvenience.

Case IX.—Cheloid. March 7, 1902. Patient, a young lady, Miss E., aged twenty-one years, referred to me by Dr. Robert T. Morris, had unsightly cheloid on the neck. On a trip up the Nile she had contracted variola; three pustules had formed and in one of these the cheloid grew. Dr. Morris removed the cheloid by the knife, but it promptly returned; he removed it again, and again it returned, larger and more vigorous than ever before. Under these circumstances a third operation was deemed inadvisable. It now measured two inches in length by three-quarters of an inch in breadth and one-third of an inch in height. It was bright red, of cartilaginous consistency and permeated by a rich and fine network of capillaries.

Fig. 7.—Alopecia Areata.

Treatment: *X*-ray, high tube, powerful *x*-ray, nine inches distance, shield, three times weekly. The shield left exposed an area of sound skin one-quarter of an inch around the growth, in order to be sure of including the entire edge of tumor within the influence of the radiation.

At the third treatment the tumor looked and felt "flabby" and was soft. Soon extensive dermatitis was established on the ring of exposed sound skin, but in the cheloid tissue itself the dermatitis was much more severe and the mass discharged serum and pus.

By May 22 (twenty-seven treatments) the inflammation seemed to be too great safely to proceed further and treatments were suspended.

June 7: Patient returns. Cheloid has greatly reduced. It measures about one inch by one-quarter of an inch, is flattened to the level of the sound skin, and offers little sensation of thickness to the touch. Patient now left the city for the summer under promise to report in the fall.

October 20: A small ridge of cheloid tissue remains at one end of the original tumor, but otherwise the cheloid has entirely disappeared.

To this spot three treatments were given, making a total of thirty treatments.

November 11: Nothing whatever now remains of the cheloid. The skin is soft and smooth.

Across the former site of the cheloid runs the thin linear cicatrix of the last operation. On either side of it a still somewhat pigmented area represents the space occupied by the cheloid. No cicatrix or scar tissue has resulted from the *x*-ray treatment.

Practically the actual time occupied in treatment was from March 7 to May 22.

Case X.—Cheloid. October 1, 1902. Mr. McF., cheloid on neck. Began about four years ago at the site of a linear scar on the neck. It now measures three inches in length by one-half an inch wide and is elevated quite one-half an inch. Ingrowing hairs of the beard within the mass cause him much annoyance.

Treatment: *X*-ray.

November 11: Cheloid growth highly inflamed and appears like a raw sore exuding serum and pus. It is flattening out and diminishing in size rapidly.

December 16: Still an open granulating surface. The amount of serous and purulent discharge is great. To palpation no cheloid thickening can be felt except a small spot at one end, apparently not so fully exposed to the *x*-ray as the rest of the tumor.

January 27: Open sore entirely healed over. Site of tumor flat and on level with sound skin. As the cheloid tissue finally retreated the patient removed from time to time three hairs about one and one-half inches in length which had been left freely exposed. The original linear cicatrix not before discernible has also come plainly to view, and, as in the prevous case here reported, on either side of it remains a pigmented area of sound and normal skin. And, as in that case, so in this, the result has not been the formation of a cicatrix but simply a retreat of a diseased condition leaving behind it a normal skin. Cheloid completely cured.

Case XI.—Acne, April 3, 1902: Miss E. B., aged twenty-one years. Acne of face, chest, and shoulders. Disease began at the age of thirteen, first as red spots upon the nose, and has since spread over the entire face and on to the neck, chest, and shoulders.

The patient experiences what she terms "bites." There is first a stinging sensation, then a small white patch, which quickly swells to a reddish or purplish lump, at the top of which a small drop of serum appears. The lump subsides in about an hour. The face is scarred and "lumpy," thick with comedones and of a dull, dusky-red, dirty color, constituting a muddy and raw complexion very disagreeable to look at. The nose is thickened and, of coarse, contour from the disease.

Dr. G. H. Fox kindly confirmed the diagnosis.

Treatment: *X*-ray to face, suspending a lead disc three-quarters of an inch in diameter by adhesive plaster before each eyeball to defend the retina. Also shield for hair of head.

May 1: A continued dermatitis of a bright red has now been maintained for two weeks. There is a remarkable cleaning up of the acne, and the face complexion is becoming decidedly fine and velvety.

Fig. 8.—Epithelioma of face not cured by *x*-ray.

June 3: Now and then a "bite" coming to a pustule. Skin of face, even to that of the ears, cleared up. The nose, which used to feel "thick and podgy," has resumed its normal shape.

At the same time the patient's general health has much improved. Her headaches have disappeared, also a general feeling of sleepiness. A distressed feeling of the stomach with frequent nausea and retching has ceased, and she can eat any sort of food without subsequent discomfort.

June 7: Some hair falling out at top of forehead.

Face shows severe *x*-ray burn and is scaly, dry, and purple red.

June 21: Last treatment on June 11. Came for treatment June 14, but the face was too purple, red, and swollen to risk another application. Applied "cold cream." Face intensely red, but in three days the swelling subsided. During this week serum has flowed freely from the surface of the

Fig. 9.—Sychosis.

skin of the face and from the swollen lips. The skin burned and itched until the watery flow was established, then it felt comfortable. The eyebrows have fallen out and the lower lashes; the upper lashes still hold on fairly. The skin of the face has entirely peeled off, and a new skin is appearing clean and delicate and pure as that of a healthy baby. The nose likewise is fine in contour and entirely clear of disease and has a delicate new skin.

June 25: Remains of dermatitis are now simply a rosy color and the skin is of a fine healthy and beautiful texture, with, of course, no sign of the former acne. The neck and shoulders shared in the transformation.

Patient cured.

Duration of treatment about two months; total number of treatments 26.

Subsequent Note.—October 8: Patient called to report results. The face presents an absolutely perfect and fair complexion and without any sign whatever of disease. The eyelashes of both the upper and lower lids fell out completely just after the patient's last visit of June 21. Also at about the same time the eyebrows peeled off completely with the skin. In three or four weeks the eyelashes began to reappear, at first quite fine and light, but as they grew longer they grew blacker and stronger and are now fully restored. In about seven weeks the hair of the eyebrows returned. The hair for one inch back of the top of the forehead extending from ear to ear fell out, but is now growing luxuriantly and has attained at the present moment one inch in length.

Case XII.—Alopecia areata, Fig. 7, April 11, 1902. Began seven years ago with a spot the size of a five-cent piece on the back of the head. The hair fell out, and from that time on to the present new and large patches have continuously appeared. The new hair would grow in snowy white and the coloring matter only appear after a growth of about one inch in length had been attained. Perhaps in six months the hair would again fall out in patches. It is not my purpose to report this case in full, but merely to point to Figure 7 and to a large patch of dark luxuriant hair of an area about as large as the palm of one's hand, indicated by the arrow. When perfectly bald, *x*-ray treatment of this spot was begun, with the usual technique referred to in this paper. The hair at first continued to fall out. On May 2 it ceased to fall. On May 5 signs of growth of the hair in the denuded area began to appear. Treatment continued until July 1.

September 8: Patient returns after an absence of two months to report that the hair had grown luxuriantly in the formerly denuded part, and that for the first time in her experience it had grown in black from the start.

At last reports, now about four months ago, the new hair remained. In the cut, Fig. 7, below the spot treated, is shown an untreated spot.

The favorable effect of the *x*-ray, is clearly demonstrated by the result in the large area alone treated by it.

Case XIII.—Sychosis of the upper lip and chin. S. S., aged forty-two years. Has had sychosis on the chin for five years and upon the upper lip for two years. Patient has tried faithfully innumerable treatments with no avail and states that nothing ever acted upon his disease so quickly or so thoroughly as the *x*-ray. The skin presents the usual nodules, papules and pustules and is deeply infiltrated. Fig, 9 illustrates the case better than would further description. Fig, 10 represents the case after six treatments, three times weekly.

Fig. 10.—Sychosis.

There is now no infiltration and no sign of the disease. The hair of the upper lip fell out at the end of two weeks. With the danger of relapse characteristic of this disease in mind, treatment will be prolonged for some time yet. Of my other cases this disease have shown identical results under *x*-ray treatment.

Case XIV.—Mrs. J. B., aged forty years. Fibroid tumor of the uterus.

August 4, 1902: Tumor began about five years ago as a swelling, noticeable in the iliac region. Present examination reveals the tumor to be a large, hard, rounded mass, filling the abdomen quite to the epigastrium, and resembling in contour an advanced pregnancy. Patient is "nervous," suffers from pressure symptoms and is continually subject to severe and dangerous hemorrhages. Frequently from month to month the flow of blood would not cease, and she often almost lost consciousness. The physicians summoned had endeavored in vain to arrest the hemorrhages by ergot and other measures. At times the pain attending the hemorrhages was excessively severe. She has been confined to her house now for nearly four years. I advised an operation for the removal of the tumor, but this the patient would not listen to, but begged that the *x*-ray might be tried in her case as an experiment. To this I consented.

Treatment: *X*-ray three times weekly, externally 20 to 30 minutes, very high tube whose radiation was conclusively shown by the fluroscope to have passed through the tumor. Relation of tube to the patient externally was frequently changed.

August 25: Patient *x*-rayed nine times and reports that her menstruation had occurred with almost no pain, with almost scanty flow, and that

Fig. 11. Case 16.—Lupus vulgaris.

this had been the first time for years when she had not been obliged to take to her bed and remain there, and take large doses of ergot and often summon a physician.

November 30: About three months' time and thirty-nine treatments to date. The tumor itself has reduced at least one-third in size and a complete symptomatic cure is obtained. The menstrual periods are regular, natural, and painless, and no hemorrhages whatever have occurred since treatment was begun. The *x*-ray therefore in this case has restored menstruation to normal, arrested the condition of severe and dangerous hemorrhages, and produced a symptomatic cure, together with a very considerable reduction in size of the growth. The patient can now get along very comfortably, but wishes soon again to resume treatment to see how much more can be attained.

Case IV.—Psoriasis. Mrs. H. C. J., aged thirty-three years. Disease began when she was ten years of age, with a small patch beneath the eye. From that time on the patches have increased in number and size and have extended in large areas almost over the entire body, mainly on the back and toward the hips, the neck and chest, knees and elbows, and general extensor surface of the limbs, and has also invaded the scalp. There are many individual patches on the body larger than the combined area of two hands. A detailed description of the disease is not essential, since its characteristics are entirely classical and typical and a picture of similar cases may be seen in any classical atlas of skin diseases. The patient had taken many kinds of treatment during all these years and without success. I had tried the brush discharge and statical electricity also, unsuccessfully. The patient was then put upon *x*-ray treatment. A large and powerful tube was provided, of high vacuum, and the patient, thinly clad, stood before the tube, taking the *x*-ray over the entire body for about half an hour or more, three times weekly. The patches of psoriasis began to thin and ceased scaling, and reduced in activity immediately after the first week's treatment. By the end of the second week at least thirteen large patches had entirely disappeared and the skin where these had formerly existed was perfectly normal, and by the end of the third week it was impossible to find the previous locality of many patches. By the end of the fourth week the arms and neck and back were perfectly clear of disease and the legs presented but faint blushes showing the locality of the disease. At the end of six weeks the patient is entirely cured, and, curious to relate, the patches on the scalp ceased at the same time, although no treatment had been applied to them specifically on account of a fear of affecting the hair unfavorably. Indeed, the patient wore a lead mask to protect the hair of the head. The fact that the scalp patches have been cured would seem to indicate that the effect upon this disease has been constitutional, as well as local, and taking into consideration that the *x*-ray thus generally administered acts as one of the best nutritional tonics to the general health, it is not strange that this should occur. Of course, in this case the usual possibility of a recurrence must be taken into account, but the rapid disappearance of extensive psoriasis in this short space of time establishes beyond question that the *x*-ray is a most potent form of treatment for this hitherto intractable disease.

Case XVI.—Lupus Vulgaris. Miss H. M. T., aged fifteen years, Halifax, N. S. At eight months of age mother noticed a small lump, size of a pea, on the left cheek. In three weeks this formed an abscess which was lanced and it appeared to be well. Soon after this noticed that the spot was becoming red, and the redness spread slowly but surely, until at two years of age it was the size of a silver dollar. The physician applied caustic and other agencies freely and frequently, but to no avail. Later on, the lupus, now larger than a silver dollar, was curetted several times, but still increased in size and activity.

Examination, 1902. On the patient's left cheek is a dull red patch measuring one and three-quarters by two and one-quarter inches and spreading aggressively on its anterior and lower borders, while posteriorly the color is paler (Fig. 11.) This patch is elevated above the surface of the cheek, firmer at its edges than in the center, and throws off fine scales. The infiltration extends deeply into the tissue of the cheek.

Microscopical examination by Dr. H. T. Brooks of the Post-Graduate Hospital Laboratory establishes the diagnosis.

I first tried in the treatment of this lupus, during a period of about two months, a fairly mild *x*-ray, producing simply a mild dermatitis of the adjacent sound skin. The lupus at first became swollen, and puffed up and looked angry, then gradually showed a shrinkage in its area and gave off large, flat scales. It presented a concavity instead of a convexity, and became saucer-shaped, but did not entirely subside,

although showing a profound reaction and a great disposition to repair.

Becoming weary of mild treatment, I substituted more powerful treatment. An aperture in a lead shield was cut, so that one-half an inch of normal skin around the edges of the lupus was fully exposed, and the *x*-ray treatment was then carried on three times a week until the sound skin presented an angry purplish red *x*-ray dermatitis, while at the same time the lupus itself began to appear swollen, angry looking, very red, exuding serum, and elevated. The normal skin was thus left exposed for a control and guide as to the extent to which the *x*-ray could be safely pushed, the presumption being that the lupus area would receive a due and proper amount of treatment within the limits of severe dermatitis upon the normal skin. This management of the case was eminently successful, for upon ceasing treatment at a time when the severe limit of dermatitis of the skin had been established and the lupus itself had been excited to an angry condition, the *x*-ray was stopped, and the lupus over a period of two or three weeks went on by itself without further treatment to a complete cure. The lupus area healed without the production of scar tissue, and the skin previously occupied by the disease is now as sound and natural as any skin of the face.

I am now treating all cases of lupus by using the sound skin as a control of the treatment, as above described, and find this method more successful than either milder or more excessive treatments.

10 East Twenty-eighth Street.

---

**The Limits of Variation in the Depth of the Mastoid Antrum.**—From a series of measurements, P. D. Kerrison concludes: (1) That in operations upon the mastoid process the antrum should always be approached from the nearest point upon the mastoid cortex, which, in the great majority of bones, is the small triangular space behind the spine of Henle. (2) That this point of attack not only furnishes a guide to the site of the antrum, but also gives fairly accurate data as to the depth beyond which it is not safe to proceed. (3) That the depth of the antrum is always less than the length of the postero-superior wall of the meatus; that in the great majority of bones it is not over 12 mm., is often very much less, and is never greater than 15 mm., or ⅝ inch; and therefore (4) That in a surgical attempt to expose the antrum a depth of ⅝-inch should be regarded as the extreme limit of safety.—*Archives of Otology.*

**Sulphocarbolate Treatment of Cholera Infantum.**—William F. Waugh says that every case of summer complaint, enterocolitis, and cholera infantum that he has attended in the past twenty-five years has recovered under the use of the sulphocarbolate of zinc. His method is the following: Clear the bowels with castor oil, calomel, mercury and chalk, aromatic rhubarb, lavage or colonic flushing as seems best in each case. For lavage he prefers a solution of zinc sulphocarbolate, a grain to the ounce; for colonic flushing the same, for rectal flushing or when the type is dysenteric, silver nitrate, two grains to the pint. The solution should be as hot as bearable. Then follow with zinc salt, from one-sixth grain to two grains every hour. He has given the latter dose hundreds of times to children in their second summer, without irritation. Some take the medicine in solution, others in granule or tablet form, but if there is a decided irritability of the stomach, it is best in powder with bismuth and pepsin. When there is extreme acidity, marked by excoriation of the rectal mucosa, etc., sodium sulphocarbolate is preferable, or the triple salts, zinc, sodium, and lime, may be used with advantage.—*Alkaloidal Clinic.*

## CONGENITAL LARYNGEAL STRIDOR.*

By JAMES E. NEWCOMB, M.D.,
NEW YORK.

During the last few years the writer has seen three cases diagnosticated as the so-called congenital laryngeal stridor, and though the circumstances in each case have been such that it could not be followed, and its later history obtained, he has been deeply interested in the study of the subject, and has deemed it one not unworthy of the attention of this association. The literature is not voluminous, and pretty much all that has been written has come under examination.

By the clinical term describing the condition is meant a stridor coming on within a few days of birth, continuing for a certain period, measured usually in months, but possibly in years, apparently not doing the child much if any injury, and finally subsiding of its own accord without sequelæ. It seems to have been first described by Rilliet and Barthez in 1853. It has been variously termed "Inspiratory Stridor of Nurslings" (Avellis), "Stridulous Respiration of the Newly-born" (Comby), "Clonic Glottis Spasm of Nurslings" (Löri), "Respiratory Croaking of Babies" (Gee), "Posticus Paralysis of Infants" (Robertson), and "Congenital Laryngeal Stridor" (Rocaz, Suckling, Stamm). No therapeutic measures have seemed to shorten or essentially modify its course. Consequently the literature has mainly concerned itself with theories of etiology and criteria of differential diagnosis.

As frequently happens in the case of rare diseases, some of the writers have endeavored to establish, from a very limited experience, a too rigid symptomatology, and in the light of our present knowledge have too sharply drawn the lines of their clinical picture. This fact is illustrated in the statements collated on the topic in the recent book of P. Watson Williams. Thus he remarks that "the usual physical signs of obstruction are presented during the exacerbations, such as cyanosis, retraction of the epigastrium and lower ribs, and depression of the supraclavicular fossa and episternal notch." On the other hand, the majority of those who have described the condition deny the presence of these clinical features. No such evidence was presented in the cases seen by the writer.

The malady seems to predominate in male babies, though no reason is assigned therefor. In so far as laryngeal examination has been applicable, it has revealed a malformation of the laryngeal vestibule, epiglottis, and aryepiglottic folds. The epiglottis has lacked its normal curvature, being folded on itself, so that its shape has been that of an arched or curved roof; or, the aryepiglottic folds have been devoid of their usual firmness, and their free ends, being thin and flabby, have nearly touched. In some instances the upper part of the larynx has seemed contracted by protuberances capable of vibrating and of playing the rôle of supplementary cords. In a second and less marked variety, the changes have been rigidly confined to the epiglottis and aryepiglottic folds, the former being rolled on itself like the end of a flute, the folds themselves approximating only anteriorly, and the *ensemble* vibrating under the effect of the air.

The causes of this condition are not always easy to find. In view of its suggestion of the familiar laryngismus stridulus, and the fact that many cases of the latter occur in rachitic subjects, some have supposed that rachitis is at the bottom also of congenital stridor. In a general way the most common

*Paper presented at the twenty-fifth annual meeting of the American Laryngological Association, held at Washington, D. C., May 12–14, 1903.

causes of laryngeal spasm in children are rachitis and digestive disturbances; to these may be added reflex disturbances from lesions of the nasopharynx, brain, and respiratory lesions. In the experience of certain observers the stridor cases have been badly nourished, but this is contrary to common observation. Some have regarded the stridor as merely a modification of the nervous mechanism of the larynx, which is within the limits of health, and is analogous to the cardiac arrhythmia observed during the first years of life (Politzer). As a rule there has been no tendency to cyanosis or convulsions such as would indicate air-hunger. The overwhelming testimony has been to the effect that the health has generally been good. In fact, the disorder has been looked on as "more an annoyance to others than to the child itself."

The time of onset may be any period from the first day of life. In the eighteen cases reported by Sutherland and Lack, the onset occurred on the first day in eleven. These authors believe it rare to have the onset delayed after the second week. The character of the sound made varies considerably within type limits. It may be a stridor, a croak, a cluck, etc. The inspiratory sound may be the louder. With superficial breathing it may completely intermit, to be reproduced and become continuous when the breathing becomes deep or irregular. It is increased by changes of temperature, excitement, sudden waking, coughing, sitting up in bed, too rapid feeding, and flatulency. It sometimes stops when the position of the child is changed from the back to one side, or when the head is placed at a lower level than the body. (Gähnen.) It continues during sleep, though never aggravated thereby, and persists during chloroform anæsthesia.

Mendez has reported one case, that of a child of seventeen months, in whom stridor accompanied and was synchronous with inspiration; then ensued a period of quiet expiration for about one-third of the expiratory period, when the stridor reappeared and accompanied expiration to its close. At other times the breathing appeared to assume the Cheyne-Stokes' type. Mendez was inclined to refer the inspiratory stridor to the pharynx and not to the larynx.

Goodhart states that respiration is accompanied under certain circumstances by a curious clucking or croaking sound, instead of by a true stridor, and that the latter is practically constant in expiration as well as in inspiration.

In view of the scattered reports of the cases and the fact that no one writer has seen very many of them, it is not surprising to find a wide diversity of theories as to the underlying cause of the condition. Let us consider *seriatim* the various hypotheses submitted.

1. *Thymus Enlargement Causing Pressure.*—In referring to a case of Herzfeld's, Avellis states his belief in this theory and believes that the lesion may prove fatal. A woman of thirty years came under his observation, having a narrowed trachea referred to thymus pressure, She had suffered from stridor in infancy, and it recurred on violent exertion after she had grown up. He reports another case in which removal of a part of the thymus relieved the stridor, or at least the stenotic symptoms. Stamm denies that true laryngeal stridor is ever due to this cause. It is an undeniable fact that thymus enlargement has not been present except in a small proportion of cases; when present, there has been expiratory as well as inspiratory stridor.

2. *Cicatricial Band across the Larynx.*—This theory can hardly be regarded as tenable. If it were, we should expect to have children born with stridor, but of such instances we have no such record. Laryngeal bands in infancy are uncommon, and are generally referable to some pathological process as syphilis or diphtheria. A few cases of congenital laryngeal bands or webs are on record, but these cases have not presented the stridor of which we speak. The diagnosis of the condition in the earliest period of life is most difficult, often only conjectural. Such cases are apt to suffer in the later period of life from dyspnœa on the slightest exertion.

3. *Acquired Brain Lesion Causing Anatomical Deformity.*—Stamm reports a case of stridor, the child dying in convulsions soon after birth. The respiration was very rapid, running from 150 to 200 per minute. There was a deep inspiration and then a relatively long pause. The child had fallen on the head during the completion of the parturient act, and there was probably some central disturbance, but the respiratory abnormality did not come on till the fourth day of life. The seat of the trouble was considered to be in the region of the calamus scriptorius, in which locality, according to the researches of Semon and Horsley, lies the coördinating center for involuntary laryngeal movements.

4. *Lack of Development of the Cortical Centers of Respiration, Especially of the Laryngeal Centers.*—Evidence on this theory is manifestly only conjectural. Autopsy alone could verify the truth of any such hypothesis, and such testimony is lacking.

5. *Posticus Paralysis.*—This theory has received the advocacy of W. Robertson, who reminds us that bilateral paralysis of the abductors with secondary contraction of the adductors is a common phenomenon in nervous pathology. He finds the starting-point of the process in irritation arising from the region of the pharynx and postnasal space. It is probably transmitted to the region of the medulla, there exciting and exhausting the accessory vagus, and this leads to the depraved innervation of the muscles in question. The latter structures are also acted on unfavorably by the collateral catarrh of their enveloping mucosa.

The position of Robertson has been vigorously attacked by Semon, who regards the cases ascribed to paralysis as being due to spasm. In such cases he notes (Heymann's Handbook) that the cords come together in such a way that the rima glottidis remains closed for an instant while, with the beginning of expiration, the cords separate. He would regard the condition of Robertson's cases as analogous to that described in adults as "perverse action of the vocal cords." He admits that in children it is often difficult to distinguish between clonic inspiratory spasm and bilateral paralysis of the abductors. In both there is a constant stridulous breathing with a free voice. Laryngeal examination in young children offers the most severe difficulties, and in both conditions, the laryngeal image is very similar at the height of inspiration. Points of difference are (1) that in spasm the stridor usually disappears during sleep, though this is not always the case, and (2) bilateral paralysis of the abductors in nurslings has never been positively determined. At any rate, it is a very rare affection, and in cases such as those reported by Robertson, Semon maintains that the *a priori* conclusion is that we have to do with clonic spasm rather than with paralysis.

6. *Muscular Spasm, Either Glottic or Subglottic and Possibly Phrenic.*—McBride would regard the laryngeal stridor cases as due to spasm and not to paralysis. He would consider them as similar in etiology to laryngismus stridulus, adding that this view is probably correct in so far that both are due to cortical irritation, yet admitting that there are marked clinical differences.

7. *Adenoids.*—Eustace Smith advanced the theory that the condition is due to adenoids in the nasopharynx, placing himself on record as never having failed to find the latter or a thickened granular state of the mucosa. One of his cases was cured by curetting of the vault. In this case the larynx was of normal size and development. Jackson has reported the case of a boy of seven months with stridor and adenoids, but removal of the latter did not cure the former, which persisted eight months longer and then gradually disappeared. In reply to Eustace Smith, Lack contends (1) that the stridor in Smith's cases was increased during sleep, (2) that it ceased under chloroform anæsthesia, (3) that it was increased by closure of the mouth in feeding, and (4) that the patient was subject to suffocative attacks, such as are very common in adenoids, but very rare in the affection called congenital laryngeal stridor. In reply to Smith's contention that stridor is caused by the spasmodic closure of the aryepiglottic folds, and that this spasm is due to the irritation set up by the adenoids, Lack replies that the spasm is probably due to the examiner's finger and the presence of the mirror in the infant's throat—a not uncommon reflex.

Finally we come to the theory advanced by Lack himself, and the one that has met with the most general acceptance.

8. *Congenital Deformity of the Superior Laryngeal Aperture Aided by the Flaccidity of the Parts in Infancy but Not Entirely Dependent Thereon.*—The upper laryngeal aperture acts as a valve. Its lateral walls fall in during inspiration. As the patients grow and the parts become firmer this lateral prolapse gradually ceases. In this theory Thompson and Logan Turner agree, and they have reproduced the stridor in the cadaveric larynx of children by imitating forcible inspiration through the glottis. Thompson believes that in life the laryngeal deformity arises from disturbance of respiratory coördination resulting in a constant sucking in of the upper margins of the infantile larynx, "a process strictly analogous to the formation of pigeon-breast."

Naturally but few cases have afforded an opportunity for the examination of the larynx. Numerous variations occur in the few statements on record. Rocaz reports one case in which the epiglottis was bent from without inward. In another case by the same author it is said that the aryepiglottic folds were hypertrophied so that the true cords could not be seen. The mother of the last-named patient was tuberculous. Rocaz suggests that nervous heredity may be a factor in the problem. In his first case, the father was bitten by a mad dog about the time conception occurred in the mother, and he considers that this fact suggests a possible toxic infection.

In one of Gee's cases the larynx was easily seen and appeared normal. Lees found the epiglottis excessively curved in its vertical axis, as if it had been bent in half down the middle, and then the aryepiglottic folds brought almost into apposition, leaving only a narrow chink between them. Sutherland and Lack examined the larynx by passing the index-finger of the left hand over the tongue and hooking its terminal phalanx around the hyoid bone, which was then pressed well forward. The epiglottis was found folded on itself, the aryepiglottic folds were approximated and the laryngeal entrance was reduced to a narrow slit, their flapping folds seeming to bound the aperture. Examination of the nasopharynx was negative.

In a few instances post-mortem examination has been made. Lees reports one case dying of diphtheria at the twelfth month. Examination of the larynx one month previously had revealed its upper aperture as a narrow median slit extending from above downward, the epiglottis being folded on itself so that the posterior surfaces of its lateral halves were almost in contact. In the case of Refslund, the parts had the shape of a jews-harp. In another instance autopsy showed, in a boy of two and a half years, the epiglottis furrowed in the middle. The furrowed part separating the cartilaginous leaves was fastened throughout by a connective tissue band to the base of the tongue. Into this furrow the epiglottis was bent so that the inner surfaces of the lateral halves touched. This latter condition Refslund considers one always to be thought of in explaining mysterious cases of laryngeal dyspnœa in children. This latter statement, however, casts doubt on the correctness of the diagnosis in this special case, for in true congenital stridor, dyspnœa is wanting—in fact, its absence is one of the most striking features of the disease.

Variot reports two cases. His first case was that of a boy brought to the hospital with laryngeal hoarseness. No diphtheria could be made out. The voice was clear in cry and speech. He was intubated, but dislodged by coughing the tube from the glottis, and it started down the œsophagus but was recovered by the thread. The mother stated that normally the stridor was present during sleep and nursing. A second tube was inserted, but was in a few minutes rejected. As far as could be ascertained, the epiglottis seemed folded over the tube. The patient died of scarlatina and bronchopneumonia. Autopsy showed the epiglottis elongated so as to form a trough from approximation of its lateral borders. The aryepiglottic folds, instead of diverging in the usual V-shape, formed a slit 1 c.m. high, and were in contact. Variot had another case with adenoids, but curetting did not relieve the stridor.

*Prognosis.*—In weakly children the condition may lead to thoracic distortion and may prove fatal. As a rule it passes off by the end of the second year. It may return during periods of excitement or of ill health. It generally increases in severity for some weeks after its appearance, then becomes stationary until about the eighth or ninth month, and then gradually diminishes until a period from the eighteenth to the twenty-fourth month, when it disappears.

*Differential Diagnosis.*—This is called for from (1) papilloma, (2) catarrhal laryngitis, (3) essential spasm of infants, (4) phrenoglottic spasm, (5) congenital retraction of larynx, (6) paralysis of dilators, (7) hereditary syphilis, (8) retropharyngeal abscess, (9) adenoids, and (10) laryngeal stridulus. The latter alone need concern us here and now. Laryngismus stridulus is favored by the onset of the first dentition. The patients are rachitic and may have tetany, convulsions, or other nerve disturbance. The spasms are of long duration and the patients become cyanotic. Crying may set the spasm up or aggravate it, and attacks are more frequent during night hours.

Stridor comes on soon after birth. It is slight and there is no cyanosis. Crying usually stops it. Deglutition has no effect upon it. Sleep never aggravates it and may stop it. In other words, we have to do with a condition in which there is a temporary anatomical deformity and an alteration of the relations between the muscles of the throat and those of the larynx. There may be the added factor of a central nerve disturbance. Some cause may act on the adductors more strongly than on the abductors. Semon and Horsley have shown that there are cortical fibers for adduction, but none for abduction. It is also furthered by backward development and irritable weakness of the

central mechanism controlling respiration, just as the tendency to laryngismus in a rachitic child has been referred to a deficiency in the higher controlling centers. In other words, there enters into the question the factor of a developmental neurosis. It is analogous to occupation spasm, urethral spasm, and stammering.

*Treatment.*—Robertson orders ammonium bromide, alkaline sprays, and resorcin in mineral oil. He also advises the clearing out of the pharynx and nasopharynx before secondary contracture sets in. Such a therapy is based, of course, on his theory of etiology. Variot has suggested partial resection of the aryepiglottic folds if dyspnœa should ensue and threaten life. Merklen and Devaux summarize treatment as bromides, strychnine, warm baths, eucalyptus inhalations, and antisepsis of the upper-air tract. On the basis of the theory which we have accepted in this paper, a general tonic régime is all that is called for.

Dr. D. Bryson Delavan has kindly sent me the notes of two cases that have come under his personal observation. Case 1 was that of a boy, now thirteen years old, who has suffered from birth from laryngeal stridor. At first it was so severe as to threaten life. Exertion now of any kind brings on an attack. Removal some time ago of a pharyngeal adenoid was followed by a distinct improvement in the severity of the condition. At present there is a slight laryngitis, but the boy is in fair health, is moderately well-developed and ignores his laryngeal handicap, though almost any kind of exercise, such as running, riding the wheel, etc., brings on an attack. All these he does in spite of the temporary discomfort. Case 2 is that of a boy now nine years old. The difficulty began a day or two after birth. As far as is known, parturition was normal, delivery being rapid. Stridor came on every time he was put to the breast, but it did not seem to inferfere with nursing. It lasted for a short time after nursing until he went to sleep, and the total duration of the trouble was between three and four weeks when it stopped of itself. No treatment seemed called for and none was attempted.

## BIBLIOGRAPHY.

**Gout and Its Treatment.**—M. A. Auerbach, holding the uric-acid theory of gout, gives the dietetic treatment as the elimination of all nitrogenous or albuminous principles from the food. To this diet should be added natural mineral waters. The medicinal treatment consists of alkalies and purgatives. The author considers the quinate of piperazine (sidonal) the best remedy; while it is not so rapid in its effect in relieving the pain of an acute attack of gout as some others, it nevertheless exceeds all others in value. During an attack it should be given in doses of ten grains every hour and a half to two hours, dissolved in at least eight ounces of distilled water. Sometimes a hypodermic injection of morphine is absolutely necessary to relieve the pain in a paroxysm of gout. As many old subjects of gout have contracted kidneys, the use of morphine under these circumstances is attended with some danger, and the drug should be administered with great caution.—*Buffalo Medical Journal.*

# PERICHONDRITIS OF THE LARYNX, WITH REPORT OF A CASE.*

By EMID MAYER, M.D.,
NEW YORK.

Diseased conditions of the larynx as a complication or sequel of typhoid fever are by no means rare and their presence may be of diagnostic value. Schmidt, speaking of the aids to early diagnosis of typhoid fever, says that inflammation and infiltration of the epiglottis form a characteristic condition and enable us to make the diagnosis of typhoid positive. Kobler, on the diagnostic value of affections of the epiglottis in typhoid, reports two cases: "There was much infiltration and deep ulceration of the epiglottis in both cases and white cicatrices resulted. Aside fom the differential diagnosis, this condition is of value in prognosis—as long as the infiltrate exists the typhoid is still at its height. In all cases of cicatrices of the epiglottis, inquiry should be made for previous typhoid to avoid a diagnosis of lues."

The more serious conditions, stenosis resulting from typhoid fever, occur from time to time, and there are a considerable number recorded in the medical literature, yet in the individual experience of most physicians they are certainly rare.

Morrell MacKenzie says: "My statistics are not at all reliable as regards the relative frequency of perichondritis in different affections, for whilst I see many cases of tuberculosis, cancer, and syphilis, I scarcely ever meet with typhoid fever; indeed, all the cases of that disease in which I found disease of the cartilage came under my notice formerly, at the time I was physician to the London Hospital." Landgraf has bibliographic reference to two hundred and sixty-six articles on this subject in Heymann's Handbook. According to Keen, the large majority of these cases occurred in Germany and on the Continent, fewer in the British Isles, and still fewer in this country. A search in the twenty volumes of the American Laryngological Association fails to note the report of a single case from its members. Some of our textbooks fail to mention its occurrence, others barely note that it may occur, while Keen, Bosworth, Kyle, and Newcomb give it more extended notice. The logical sequence of these facts is that the statement that stenosis of the larynx consequent to typhoid fever is much less frequent in America than elsewhere is proven.

Pathologically it may be considered to occur in the following manner: Commencing with hyperæmia and congestion there rapidly follows an inflammatory œdema with exudation into the surrounding or adjacent soft structure, which on account of the location and the limit set by the cartilaginous wall of the larynx must extend inward and rapidly lessens the lumen of the larynx. This œdematous stage and the stage of ulceration which has gone on to necrotic involvement of the cartilages differ only in degree but not in kind. The cartilages of the larynx are at best poorly supplied with blood, rendering them at all times susceptible to necrotic change. When, during the course of typhoid fever, the nutrition is lowered throughout the body, circulation in this locality suffers to a greater extent, as it is dependent on surrounding tissue for its blood supply and rapidly undergoes necrosis which may slough out in small pieces or be discharged *en masse*. This breaking down of tissues, as in abscess formation, may penetrate toward the point of least resistance, rupture

*Read before the American Laryngological Association at its twenty-fifth annual meeting held at Washington, D. C., May 12-14, 1903.

and virtually form an ulcer. In the majority of instances of perichondritis or chondritis due to typhoid fever, the infection and inflammatory process are similar to those seen in abscess formation, which, making for the point of least resistance, open in ulceration on the mucous surface. The ulceration is only situated posteriorly and the cartilaginous inflammation on the side and toward the back part of the larynx. Thrombosis may take place in this area due also to the added weight of the decubital position. If only a part of the cartilage has been destroyed and the perichondrium remains, there may be a reproduction of the cartilage; in any event, it is likely that the abscess will be followed by a fistula and suppuration without necrosis of the cartilage may occur.

Other and varied views as to the pathology of this condition have been expressed. In a paper read before the Laryngological Society of London, Kanthack and Drysdale said that these defects are situated generally over the tip and edges of the epiglottis and in the neighborhood of the processus vocalis. It is not true that the laryngeal lesions invariably appear during the acute period of the fever before healing commences. They support Rheiner's view that the ulcers are produced by small repeated injuries acting on debilitated tissue. They declared as incorrect the view that the ulceration affects the adenoid tissue of the larynx, for along the tip and edges of the epiglottis and over the processus vocalis no such tissue ever develops.

The question as to whether these are specifically typhogenetic is negatived. Undoubtedly the lesions are caused by microorganisms; there is the strongest evidence that these are the pyococci, and not, except rarely, the typhoid bacilli. While the latter may be the cause, the soundest possible observations are necessary to make them convincing. The ulcers occurring during the course of typhoid fever are caused by fresh infections with pyogenic organisms which always abound in the larynx and which gain a firm foothold on the debilitated tissues, although they cannot deny that in an individual case the typhoid bacillus may have escaped and caused the lesion. In the discussion, Watson Williams, Jobson Horne, and Sir Felix Semon participated.

More recently (1902) Samuel West, in his article on "Perichondritis, Necrosis, and Caries of Cartilage," says: "In typhoid fever this lesion is usually described as commencing as a perichondrial infiltration which is held to be of the same nature, to run the same course, and to break down in the same way as the infiltration in the intestines. It is possible that the perichondritis is not primary in the strict sense of the term, but is the result of previous ulceration near to the affected part."

Among recent reports of bacteriological examinations Schulz (1898) was enabled to demonstrate the presence of typhoid bacilli in the laryngeal mucous membrane. Strazza in the Italian Laryngological, Otological, and Rhinological Congress at Rome in 1899, showed a specimen with extensive ulceration on the surface and in the deeper parts. In this preparation microorganisms in the form of cocci could be seen.

Rethi (1901) says it is now generally accepted that various, even specific affections of the larynx, are due to the bacillus of Gaffky. Finally, E. Bendix and A. Bickel (1902) make the very interesting statement that in a case of typhoid fever complicated by severe laryngeal symptoms, they found on each palatoglossal arch and on the epiglottis an elevated plaque-like area, while the surrounding tissues were unaffected. They introduced a platinum needle into one of these plaques after carefully sterilizing the surface, and obtained cultures of a bacillus that was identical with the typhoid bacillus and that gave the serum reaction with the blood of another patient with typhoid fever. The plaques ulcerated slightly, but soon healed. This seems to be the first satisfactory intravitam demonstration of typhoid bacilli in throat lesions.

Perichondritis may be present in any part of the larynx, mostly, however, in the supraglottic region. There may be infiltration alone, a deep ulceration with subsequent necrosis and extensive submucous infiltration. The case here presented is one of the latter variety:

In the forenoon of January 19, 1903, I received an urgent message to see Mrs. H. H., aged twenty-eight, native of Norway (eighteen years in the United States), in consultation. I saw the patient within half an hour and found her half lying on the bed, gasping for breath from some form of laryngeal stenosis. The livid expression of her face, the rapid, wearisome respiration, the stridor, inspirator depression of the neck and chest wall, the cyanotic lips and anxious expression of the countenance showed the unrest of despair, the struggle with death.

The history given was that on October 18, 1902, she had an attack of typhoid fever; four days later she was taken to one of our large hospitals and an unusually severe attack of the fever occurred. The temperatures were persistently high, remaining at 106° to 107° and requiring an ice bath on one occasion of forty-five minutes' duration; pleurisy with effusion, an abscess in the arm and phlebitis followed. At the end of two months she was discharged as cured on December 13.

Quite early in her illness hoarseness developed, but no laryngoscopic examination was made. This hoarseness remained and still exists. Four days previous to my seeing her, dyspnœa began on slight exertion. In spite of local applications her condition became worse.

*Examination.*—Patient much emaciated. Supported in an upright position, a good view of the larynx was obtained. On the right half of her larynx was a large mass beginning on a line with the ventricular band and extending down into the trachea, narrowing the lumen to a mere chink. Temperature 101½° F., pulse 126, respirations 36. The diagnosis of post-typhoid laryngeal perichondritis was made and immediate tracheotomy was advised. This was agreed to, and at 1 P.M., two hours later, under chloroform administered by Dr. M. L. Maduro, with the assistance of Drs. J. L. Adams and R. L. Longacre, I performed tracheotomy.

On January 20 a large œdematous swelling appeared over the right arytenoid, the larynx meantime being completely occluded. The œdematous swelling caused pain in swallowing, was punctured, and a quantity of serous fluid exuded. The tissues of the neck now became involved and there was considerable bulging, mainly on the right. On the 23d the whole neck was swollen and Dr. F. W. Murray saw the patient with us. He considered the swelling to be of an evanescent nature and advised temporizing. This was done and the swelling gradually subsided. At this time I found a large swelling occupying the posterior wall of the pharynx, which I incised and a quantity of serous fluid exuded. Her temperature now fell each day, so that on the 25th it was 100° F., respiration 22, pulse 100.

March 1, 1903: The history of the patient from

the last note up to the present time has been that of steady progress for two weeks, interrupted then by threatened phlebitis, which was avoided by the skilful care of her attending physician, and in the last few days of February she became able to walk about, and on March 11 came to see me in my office.

Examination of her larynx shows a degree of swelling extending from the false vocal cord downward. From the uppermost portion of the swelling there projects a globular mass, white in color and the size of a pea. The vocal cords, which can now be seen, are clearly white and apparently adherent posteriorly in one-third of their length. There was fixation of the left half of the larynx. There were abundant granulations about the tube externally and granulation tissue growing into the orifice of the tube in the trachea. The voice is reasonably clear. Respiration may be carried on for half a minute with the tube occluded; at the end of that time marked dyspnœa occurs.

On March 13, under cocaine anæsthesia, I removed the white globular swelling, which, on examination, proved to be granulation tissue. On the 15th, 17th, and 19th I introduced graded sizes of Schrotter's tubes. I also made various attempts at intubation with the O'Dwyer tube attached to a hollow handle devised by myself, and shown to this association at a previous meeting. These latter were not successful, owing probably to the large size of the tube. On March 19 I introduced a pair of long laryngeal forceps and stretched the larynx fully, hoping thereby to separate the adherent vocal cords. A great deal of reaction followed this procedure; there was much œdema, dysphagia lasting several days, so that divulsion had to be interrupted and sedatives applied.

March 24: Intubation by Schrotter's tubes continued with increasing sizes every other day without further dysphagia.

April 11: Examination shows the cords to be less adherent and quite some induration in the trachea immediately below the right vocal cord. Adult intubation tubes of the O'Dwyer pattern, marked five, six, and seven, were now introduced, but rested only on the vocal cords and were promptly ejected. Subsequently a No. 5 Schrotter tube was introduced, entering the trachea readily, and through this the patient breathed.

April 19: Schrotter tubes introduced every other day. Various attempts to introduce O'Dwyer tubes failed, the requisite force being too painful for the patient.

On April 20, under chloroform narcosis, a No. 7 O'Dwyer tube was readily introduced and retained by the patient. A hypodermic injection of morphine, one-fourth grain, was given. Intubation was done at 2 P.M. Patient vomited once or twice within the next three hours, but rested quietly, breathing well. At 4 P.M. she swallowed cold water in the Casselberry position and subsequently swallowed milk in the same way.

April 21: Slight vomiting at midnight, due in all probability to the morphine given at 10 P.M.

April 22: No more vomiting; coughs, swallows well in the usual position, but liquids only. Evening temperature 100° F.; morning, 99° F.

April 23: Morning temperature 100° F.; evening temperature, 102°F. Coughs less; complains of pain in her throat.

April 24: Normal temperature; swallows better; went home. Has been eating all kinds of food without discomfort.

May 11: The tube has now been worn for three weeks. Patient goes about feeling entirely well; swallows all kinds of food and has no complaint whatever.

During the last two years eight cases of stenosis of the larynx have been recorded in this country and a résumé of these is here appended.

J. P. Crozier-Griffith (March, 1900) reports a case of stenosis of the larynx after typhoid fever in a boy aged nine years. The case was seen by Dr. W. J. Freeman, who found œdema of both arytenoids and swelling of the left ventricular band and right vocal cord. Recovery.

Alexander Lambert reported a case of membranous laryngitis complicating typhoid fever before the New York Pathological Society on February 14, 1900. A male alcoholic subject entered the hospital with marked dyspnœa, severe cough, and laryngitis. Leucocytes were only five thousand, hence diagnosis of typhoid was made. At the end of the third week the temperature had fallen, and every evidence of improvement was noted. About this time the laryngeal symptoms were more severe and in three days aphonia was complete. Tracheotomy performed; patient died the same day of heart failure. *Necropsy*: A thick membrane was found extending from the epiglottis down into the larynx and into the trachea, and in the sulcus on the left side was an abscess cavity. In the membrane from the pharyngeal surface of the arytenoepiglottic fold there had been a diphtheritic inflammation and a line of demarkation had formed, causing a loosening of the necrotic tissue. A little beneath this line of demarkation there was an acute exudative inflammation with interstitial hemorrhage. Apparently there had been two infections—an earlier one causing necrosis of the surface and a later one causing an interstitial hemorrhage at the base of the granulation tissue. On the inner aspect of the arytenoepiglottic fold there was a fibrinous exudate on the surface with granulations beneath and a rather excessive diapedesis of red corpuscles. This was probably due to the second infection. Nearly all the organisms found were diplococci and streptococci.

M. H. Fussell (May, 1900) reports two cases of perichondritis of the larynx in typhoid. In the first case five days after temperature was normal, symptoms of stenosis and swelling of the external parts of the larynx occurred. Tracheotomy was advised and declined. Patient died.

Second case: Thirteen days after cessation of fever, chill. This seemed to be due to an abscess on the arm, as temperature ceased when this was incised. At this time stridor occurred on excitement and heavy respiration in sleep. Stenosis became apparent and tracheotomy was performed. Two days later the abscess broke and it was clear that death would have occurred had the cannula not been *in situ*. Subsequently the necrotic arytenoid was thrown off; there was ankylosis of the cricoarytenoid joint and fixation of cords. The cannula was worn for five months; was removed but later reinserted.

L. B. Lockard (January 30, 1900), on the laryngeal manifestations of typhoid fever, reports the case of a male aged thirty-five years. In the sixth week pain and dyspnœa, due to an abscess on the left arytenoid, occurred. Tracheotomy and endolaryngeal incision of the tumor evacuated considerable pus. The left vocal cord was fixed in adduction due to ankylosis of the cricoarytenoid articulation. The right cord was abducted and perfectly rigid, due no doubt to the perichondritis that had extended across the median line. Dilatation daily; cords readily separated, but would immediately fall back into their old position. Schrotter's and O'Dwyer's tubes were tried, but without benefit. The tracheal cannula was constantly worn except when the

patient was at rest. The cords were removed piecemeal by the curette of Heryng, with recovery as to breathing, but voice is almost entirely lost.

William B. Robertson and C. C. Biedert (December, 1901) report a case of Ludwig's angina complicating typhoid fever. Male, aged twenty-two years; during the third week of typhoid difficulty in breathing occurred; swelling on the left side of the neck, tender on pressure, board-like in hardness. Œdema of the pharynx, larynx, and epiglottis; larynx almost entirely closed. Six hours later dyspnœa requiring tracheotomy; ten hours later patient died of some myocardial change.

*Necropsy.*—Tissue about the neck œdematous and swollen, but showed no evidence of breaking down. Mucous membrane of the larynx, especially about the left vocal cord, and that of the epiglottis was œdematous, greatly swollen and almost purple in color. Cultures from the spleen showed Eberth's bacillus. Microscopic section from the larynx showed a pure streptococcus infection.

L. D. Brose (February, 1902) reports the case of a girl who had typhoid in the fall of 1899. When seen by the writer (six months later) she had paralysis of both adductors which he regarded as myopathic and due to a catarrhal laryngitis following typhoid. Recovery resulted.

F. Alan G. Murray (March 7, 1903) reports a case of typhoid fever complicated by Ludwig's angina. Death from œdema of the larynx. Male, aged thirty-two years. On the twenty-fifth day a swelling appeared on each side of the neck under the sternomastoid muscle. This swelling does not extend up to the angle of the jaw and is hard and painful on pressure. Voice harsh and metallic; dysphagia; breathing obstructed and labored. Tonsils not swollen; there is no record of a laryngoscopic examination.

At the necropsy the mucous membrane of the larynx was found congested, cords swollen and œdematous, and the passage almost closed.

Among the eight cases recently reported as occurring in America two recovered completely, two partially—that is to say, the tube is still worn—while four died. This indicates the serious nature of affection.

I am inclined to question the diagnosis of Ludwig's angina in the two cases, and believe them to have been perichondritis of the larynx of the submucos infiltrate variety.

The study of these cases with my own leads me to believe that early tracheotomy, subsequent dilatation and intubation is the best method of treatment.

My own case has features of interest: The early development of laryngeal symptoms during the disease, though unfortunately not recognized, the enormous submucous infiltration, both before and after tracheotomy, the success that followed dilatation, making intubation under anæsthesia very easy of accomplishment, and the subsequent ease of deglutition with the tube *in situ*. The extraction of the tube will show whether there is any paralysis or cricoarytenoid affection.

The further history of this case is as follows:

July 8, 1903: After wearing the intubation tube for nearly six weeks, it was removed on May 28, 1903. No discomfort followed its removal. Laryngoscopic examination showed absence of the adhesions of the vocal cord and some thickening of the mucous membrane on a line with the cricoid cartilage. Respirations were without any dyspnœa for four days; they then became more noisy and obstructive, and on June 4, six days after extubation, I reopened the tracheal wound, intending to remove any fibrous bands in the trachea. None were found, and the dyspnœa believed to be due to retraction at the site of the tracheotomy. Four days later the cannula was removed and the No. 7 O'Dwyer tube was inserted at my office under cocaine. This tube is now worn without any discomfort whatever, and will be permitted to remain until September of this year.

If, as I confidently anticipate, as a result of the prolonged intubation, the large tube has sufficiently distended her larynx for continued breathing purposes, as there is no paralysis resultant from the typhoid, I shall be able to add the word recovery, and further to claim this as the first case thus successfully treated, to record one more success for the O'Dwyer tubes and a triumph for modern surgery.

**The Etiology of Cancer with Special Reference to the Parasitic Theory.**—Frederick A. Baldwin says in regard to the peculiar bodies found in the protoplasm of cancer cells that so far no one has shown conclusively that they cause cancer, nor that they are either animal or vegetable organisms. If these bodies are not parasites, what are they? The author considers that the answer is plain. If these bodies are not stained, it is impossible to distinguish one form from another. The yellow-staining body cannot be told from the red or blue, or the final granular stage. With Mallory's combination it is possible to trace the gradual formation of the granular or end stage, which, with many of the specific stains, gives the characteristic reactions of mucin. What part of the cancer cell degenerates to form this mucin cannot now be stated, but it is very probable that it is the centrosome, since the mucin always occupies the position of the centrosome, and only the most rapid fixing agents will preserve these bodies of mucin.—*The Physician and Surgeon.*

# GOUTY PHLEBITIS.*

By A. A. GETMAN, M.D.,
AND
R. W. AMIDON, M.D.,
CHAUMONT, N. Y.

As Paget commences his classical essay on the above subject† with the words: "I have met with certain cases of phlebitis, the like of which I cannot find on record," we are led to report the following case: The father of our patient, a man of sixty-eight, died of what was called angina pectoris (first attack), but there was no post-mortem proof that the condition was *not* a pulmonary embolism. A few months before death he had suffered from phlebitis in the legs following a fall. His sister, our patient's aunt, died when past seventy, of senile (?) gangrene of the legs. An elder brother of our patient dropped dead in the street at about seventeen years of age. He is said to have had mitral disease. The patient's mother, aged sixty, died comatose, after a short illness, characterized chiefly by dyspnœa. Three brothers and a sister seem well and, until overtaken by gouty phlebitis, our patient enjoyed average good health, although suffering from obstructive dysmenorrhœa and occasional headaches of a rather migrainous type. She is about thirty-nine years of age, married, but has never had children. Her first attack of phlebitis occurred about three years ago. In January, after having nursed her husband through a rather tedious run of remittent fever, she fell from a street-car step, landing heavily on her heels. The next day she had considerable pain and tenderness in the right leg, more marked over the course of the saphenous vein, which was distinctly enlarged, tender, and hard to the touch. Its course was portrayed by a dusky, reddish line resembling the track of a lightly applied actual cautery. The pain and tenderness was continuous, and got worse, preventing rest and sleep. After a few days of great pain, discomfort, and apparently febrile excitement, the left saphenous vein became similarly affected. It was at first thought the ailment was an acute peripheral neuritis, and it was treated with ice-bags and iced lead and opium wash, the patient meanwhile being put on a very nutritious and stimulating diet with plenty of stout to drink. All the symptoms continued, and local conditions were aggravated by a tense, brawny swelling of both legs and feet. At last one of the attending physicians recalled Paget's essay, and the diagnosis and treatment were changed accordingly. The patient was put on a light diet, much to her disgust, the lead and opium wash was used warm, and iodide of potassium was given internally. The fever, tenderness, and pain gradually went away, but the œdema persisted, and it was fully five months before the patient could walk short distances, and then only with elastic bandages above tight-fitting high boots. The saphenous veins seemed occluded and felt about the size and as hard as slate pencils and, as collateral circulation seemed slow in being established, œdema and some aching pain persisted.

Anything like action or prolonged exercise on foot has been impossible since the first attack, which was followed by anæmia, treated by Bland's pills. In June of this year a partial recurrence occurred in the left leg, confining the patient to her room two weeks and rendering walking painful for two months. It is rather doubtful whether she had entirely recovered from the attack in June when she was seized with the worst attack of all about August 12. Of this no exciting cause was apparent except the fatigue of getting her summer house in order and some unusual worry. Intense pain in the region of the left saphenous vein was the most marked early symptom, with great tenderness of the part and a dusky red discoloration over the affected vein. Chilly sensations and febrile excitement with great restlessness and insomnia appeared synchronously. By the third or fourth day of the recurrence the disease had spread upward to the groin and downward to the instep. Various superficial veins on the inner aspect of the thigh, leg, and dorsum of the foot became, at different times, acutely inflamed, as denoted by local pain, tenderness, and dusky red lines, thus emphasizing Paget's characterization of the condition as metastatic. These lines were sometimes radiating or digitated, exactly mapping out the origin of a superficial vein. Here and there, in the region affected, in successive crops, there would appear dusky reddish macules from ½ to 1 centimeter in diameter.

At the height of the attack the trunk of the long saphenous vein seemed involved, as a large, tender, painful, ovoid swelling appeared over its course, right in the groin. Local inflammatory symptoms varied a good deal from day to day and, after about two weeks, gradually lessened, not entirely disappearing, however, in two months. In this last attack the disease was confined to the left side.

The local symptoms have been fully enough portrayed, except it is interesting to note that during the height of the venous inflammation the patient had her *first*, frank, gouty manifestation, namely, intense pain and tenderness in the metatarso-phalangeal joint of the left big toe, with a dusky suffusion and swelling of the foot.

The general symptoms were those of inflammation and fever. The bowels were sluggish and the liver inactive. The urine was about normal in amount but of high specific gravity and acidity. There was frequent micturition, probably due to the acidity of the urine. The pulse followed the temperature and, during the acute illness, was rapid—10 was the highest pulse counted. It was regular, except when made intermittent by quinine. The temperature was febrile for about two weeks, but never high, 100.4° F. being the highest recorded. For a time, with other symptoms, it seemed to show some periodicity, being higher on alternate days. It was always higher in the late afternoon. There was much irritability and wakefulness, due chiefly to pain (which was sometimes intense), hyperæsthesia, and an impossibility of finding a comfortable position for the limb.

All symptoms were intensified during menstruation and, during convalescence, mild, acute symptoms reappeared with menstruation for months.

Of the exact nature of the ailment and of its appropriate treatment we were at first very much in doubt. A reference to Paget's Essays cleared up the diagnosis, but helped little as to treatment, except to emphasize our caution as to complete rest in bed and the employment of heat and only soothing local applications. She had been taking lithia (gr. v. every two hours) in the form of effervescing tablets; iodide of potassium, gr. x four or five times a day, and small doses, gtt. x-xv, of the wine of colchicum seed. These continued for a few days, putting her on a diet solely of peptonized milk. After a saline purge had operated freely, she was given calumba as a bitter tonic and one or two pills of aloes and mastic each night. In the second week of her acute illness, when marked periodicity of symptoms appeared, she was given quinine sul-

*For a somewhat similar case see MEDICAL RECORD, January 18, 1890: "A Case of Recurring Phlebitis," by A. A. Smith, M.D.

†Clinical Lectures and Essays, by Sir James Paget, Bart. N. Y., 1875, p. 292; also St. Bartholomew's Hospital Reports, Vol. II. p. 82.

phate, in acid solution, in gr. v. doses and later in gr. iiss doses until, in seventeen hours, having taken gr. xviiss, very marked irregularity and intermittence of the pulse and a nearly normal temperature occurring, the quinine was stopped. While not producing a permanent lowering of temperature, the quinine did seem to break up the periodicity of other symptoms, so it was continued, in small doses, after the heart's action became regular again. Later, the salicylate of soda in gr. x-xv doses, four times a day, was substituted for it, and later still, gtt. v doses of the ammoniated tincture of guaiac were added to the iodide of potassium. For the restlessness and sleeplessness, 3 i. doses of potassium bromide had very temporary, if any, effect, and two or three nights morphine had to be resorted to, gr. $\frac{1}{10}$ giving great comfort and some sleep. Later farinaceous food was allowed in addition to the milk, of which, on the average, nearly two quarts were taken daily. Before the acute symptoms had subsided marked anæmia began to manifest itself, and a tablet of iron and quinine āā gr. i, arsenious acid gr. $\frac{1}{30}$ was ordered three times a day.

The patient was practically bedridden two months. During the next three weeks she spent part of her days in a reclining chair, but it was about three months before she could get about on crutches, and at the present writing (December 5), 115 days after she went to bed, although she says she feels, except in her leg, better than she ever remembers, the left leg and foot are still swollen from imperfect collateral circulation, indurated, and, of course, correspondingly clumsy. She is still taking small doses of mixed salicylates, Blaud's and aloes and mastich pills. While the results may seem tardy and inconsequential to the reader, to us, who for days almost despaired of recovery, and for weeks expected cardiac or pulmonary embolism, the outcome is very satisfactory. That her popliteal vein will eventually become pervious we are confident.

We are in no doubt as to the benefit, in this case, derived from complete rest in the recumbent posture, local heat, the salcylates, quinine, iron and laxatives, but we are sure the outcome would have been far less satisfactory had it not been for the assistance derived from Alexander Haig's "Uric Acid as a Factor in the Causation of Disease." This book, while shattering many of our old ideals of pathology and while playing fast and loose with some of our favorite remedies, opened up new realms in the pathology and treatment of uric-acid diseases and contributed largely to the successful treatment of this and subsequent germane cases. There no longer remains in our minds a doubt that all medicinal treatment of such conditions is only palliative, unless it is supplemented by a rigid diet, and we also fully believe that all such ailments, when not too far gone, are curable by his method. His statement that it is easier to keep uric acid out than it is to get it out when once in, needs no argument, and this he does by taking from the diet, as far as possible, all uric acid containing or generating substances. The fact that this regimen eliminates all animal foods and their derivatives (except milk, butter, and cheese), eggs and food containing them, peas and beans, coffee, chocolate, tea and alcohol. does not matter to those who prefer simple food and health to "the flesh-pots of Egypt" and chronic mental and bodily infirmity.

**A Place to Steer Clear of.**—An example of English as she is spoke, or written, is to be found in Italy in the shape of a notice placed in the entrance hall of a certain charitable and nursing establishment in Tuscany. It runs as follows: "The little fathers of the poor of St. Francis harbor all kinds of disease, and have no respect for religion.—*San Francisco Argonaut*.

## HYBRID MALARIA.

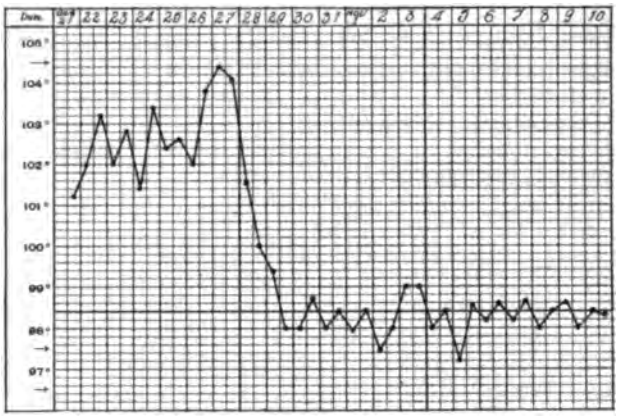
By J. LINDSAY PORTEOUS, M.D., F.R.C.S.Ed.,
YONKERS, N. Y.

For some time past there have been in this locality many cases of a disease presenting symptoms analogous to those of several well-known maladies, and which, for want of a better name, I have called "hybrid malaria."

It may be defined as a remittent continued fever, with or without diarrhœa, characterized by rose-colored spots (sometimes, however, absent), appearing at times solitary, and at other times in groups, both on abdomen and sides.

*Etiology.*—Uncertain, but seems to be caused by a specific poison which is allied to that of typhoid fever and malaria. It does not seem to be influenced either by age of person or by conditions of life.

*Invasion.*—The invasion does not seem so insidious as in typhoid, nor so sudden as in malarial fever. The first symptoms noticed are a coldness of lower limbs, feet, and hands, but no distinct chill, a sensation of fulness in the head, flushed face. Appetite may or may not be impaired. Bowels rather constipated. Abdomen slightly tympanitic. Urine high-colored and of offensive odor. A certain amount of drowsiness is experienced, but is relieved by exercise and purgation. In the second



stage there is a rise of temperature to about 99½ in morning and 100½ in evening. There is now pain in back and limbs, which gradually increases, especially between scapulæ, the temperature at same time rising to 102° in morning, and 104°, or even 105°, in evening. The pain in muscles is now very great. Insomnia is very marked. Rose-colored spots appear generally about fourth day, either isolated or in groups. They disappear on pressure, returning immediately when pressure is removed. They do not come in crops, but seem to remain three or four days and disappear. Sometimes there are groups on sides as large as a silver dollar, but the spots do not coalesce. There is no pain or gurgling in right iliac region. Sometimes there is considerable tympanitis in this stage, which is not relieved by purgation. Sometimes, but *seldom*, there is a muttering delirium resembling that of delirium tremens, and tremor of tongue, when protruded or when speech is attempted. By speaking loudly, the patient at once seems to recover himself and will answer intelligently any question put. The Widal test showed negative results in all of the cases I have used it in.

*Duration.*—One week to four weeks. In one case there was considerable diarrhœa, which would not yield to the usual treatment, but after taking one quart of an aqueous solution of acetozone in twenty-four hours it entirely ceased.

*Alimentary Canal.*—The tongue is at first white and moist. About the fourth day it becomes brown and dry. The fæces throughout are very offensive and of a dark color. Diarrhœa alternates with constipation. Sometimes there is vomiting. The following case is a typical one: E. S., aged twenty-four, married, consulted me on the 21st of October. She stated that for several weeks she had chills and fever at irregular intervals, but was able to go about her household duties until three days before I saw her, when she became nauseated and could not retain any food. She was very much exhausted when she sent for me. I found her temperature 101° (evening), pulse 120°, pale face, very weak and nervous, nausea was excessive. The bowels were loose, the discharge dark and of a foul odor. There were clusters of rose-colored spots on abdomen and side. These conditions continued until the 27th, when, under the influence of Warburg's tincture, the temperature rapidly fell, and the patient made a rapid recovery. By the 11th day of November, three weeks after I first saw her, she was able to attend to her home duties, and has since remained well. On the 27th of October she had her first dose of Warburg, and the steady fall of temperature began, as will be seen by chart.

Most of the cases I have seen were considered cases of pure typhoid, but none of these reponded to the Widal test when I applied it. All had many symptoms of typhoid, and some of the symptoms of malarial fever. On the other hand, the most prominent symptoms of both of these diseases were wanting.

*Diagnosis.*—From paratyphoid, by its having no limitations as to age of patient, by having no subnormal temperature at the beginning of the attack, and no purulent monarticular arthritis appearing on the 5th day, as is said to be the case often in paratyphoid. From typhoid, by its more rapid onset, by its freedom from complication, by absence of iliac pain or gurgling; and by the eruption not coming in crops, but often in clusters, and appearing in first week, and remaining several days, and then disappearing gradually; by the sudden subsidence of fever, and rapid recovery, and by the negative results obtained in Widal test.

From malarial fever, by the absence of intermittent febrile conditions, by the appearance of a rash, by the absence of a chill.

*Treatment.*—A calomel purge and large doses of Warburg's tincture give the best results. If the diarrhœa is obstinate, acetozone seems to overcome it.

Such is an accurate account of this, to me, peculiar disease, a disease presenting so many symptoms of some other disease, but not exactly resembling any.

83 Warburton Avenue.

## "AUTHORITY AND FACTS."

By J. R. CLEMENS, M.R.C.S. (England),
ST. LOUIS, MO.

THERE are three statements copied from textbook to textbook that, from force of repetition, have acquired what appears to me to be unwarranted guarantees. They are: (1) That early albuminuria in cases of sore throat is suggestive of diphtheria in contradistinction to scarlet fever. (2) We are told to look for *absolute constipation* in acute intestinal obstruction as confirmatory evidence of the condition. (3) In the headache of chronic renal disease the chief indication is to lower the arterial pressure. Without reservation, these three statements are absolutely valueless and for the following reasons:

I. *Albuminuria in Conjunction with Sore Throat.*—*Afebrile* sore throat plus albuminuria is willingly conceded to be highly suggestive of the premembranous stage of diphtheria, but what of *febrile* conditions accompanied by sore throat?

There is such a thing as albuminuria of fever *without* the association of any sore throat. Such being the case what is the relationship in point of time between the onset of fever and the first appearance of albuminuria. There is a certain chronological relationship between the onset of typhoid fever and the appearance of rose spots. Is there any such relationship between the onset of febrile conditions and the appearance of albuminuria? Until this question has been worked out such generalizations of differential diagnosis in distinguishing between early diphtheria and scarlet fever are relatively worthless, as how are we to tell what part the angina and what part the fever has in bringing about the albuminuria?

If we knew, from clinical observations and research, that the albuminuria of fever in general did not, for example, tend to appear before the end of forty-eight hours, an onset earlier than this of albuminuria in cases of *febrile* sore throat would be highly significant, but in the meanwhile for want of certainty the wise man will assume the worst and act accordingly.

II. *The Absolute Constipation of Acute Intestinal Obstruction.*—No one denies this condition does not exist in acute intestinal obstruction, but the difficulty lies in eliciting the fact. The books include it under *physical* signs. If so, *subjective symptoms* of the patient are included under this term. Take for example a patient who has been accustomed all his life to an evacuation of the bowels on every third or fourth day prior to the onset of acute intestinal obstruction. Let him be now seized with acute intestinal obstruction. Of what value is a history of absolute constipation? It is only a relative term. What is absolute constipation to one man is merely the natural condition of another. It is only when a patient suffering from acute intestinal obstruction *volunteers the statement that he thinks if he could pass flatus or have a motion that he would be better* that absolute constipation *per se* becomes a valuable sign of the morbid condition. It is a loaded rectum or meteorism synonymous with absolute constipation? He is a bold man who would so assert.

III. *The Lowering of Arterial Tension by Drugs in Chronic Renal Headache Cases.*—Without qualification such routine practice is distinctly dangerous. In such cases we are to sail between the Scylla of uræmia on one side (if we lower the tension) and the Charybdis of apoplexy on the other side if we do not interfere, perilous navigation certainly.

Is the headache in such cases itself a minor manifestation of uræmia, or is it symptomatic of arterial tension? This is a question we must ask how to answer. In view of the fact that a very great authority in the *English Medical World* recommends the following for the high arterial tension of chronic renal disease, the question may, perhaps, assume additional importance:

| | | |
|---|---|---|
| ℞ | Potass. bicarb. | gr. xxvii. |
| | Potass. nitritis | gr. xviii. |

## MORE GERMS—THE INFRA-VISIBLE WORLD.

IT has, of course, long been a question whether there might not be a world as vast as the visible one, lying beyond the power of our microscopes. The paper of Dr. E. Roux, in the *Bulletin de l'Institut Pasteur* for February 28, 1903, in the nature of a résumé of work along this line during the last four years, is therefore of the greatest interest. The known microorganisms exhibit great variations in size, some being as large as 3 to 6 micromillimeters in length, while the Pfeiffer bacillus of influenza measures only 0.5 micromillimeter, or $\frac{1}{50,000}$ of an inch. One-fifth of this size, however, measures the limit of visibility with our present microscopic appliances, but it is *a priori* almost certain that organic life does not stop short at just the point where we lose sight of it, and there presumably must be an entire world invisible to us.

And as early as 1881 we find Pasteur assuming that the virus of rabies is so small as to be invisible. It is, however, only since 1898 that this deduction of the existence of infra-visible life has been confirmed by observation. If a drop of lymph be taken from an unbroken vesicle in a cow suffering with aphthous fever, it appears perfectly clear, and under the microscope shows only some lymph cells, red blood cells, and very refringent granules of very variable dimensions. The granules appear at times as barely perceptible points. The most varied staining and culture methods fail to reveal microbes, but they are there none the less, as the lymph transmits the disease. These microbes are smaller than the smallest known bacteria, as further experiment shows. If one part of this lymph be diluted with thirty-nine parts of water, and the mixture passed through a Birkefeld filter of infusorial earth, a cubic centimeter of the filtrate reproduces the disease. That the filter is in good order may be proven by its arresting the passage of the *Bacillus fluorescens*. Similarly the filtrate of the mixed lymph and water retains its virulence after repeated filtration through Birkefeld filters. Yet the most powerful objectives fail to show any organisms. They are, however, present, as passage through a Kitasato filter renders the fluid inert.

Löffler and Frosch's results thus warn us that while the filters which are usually depended upon to sterilize fluids, may arrest the ordinary bacilli, much may pass through that we wot not of. Another case in point is the disease, bovine peripneumonia. This disease is characterized by a thickening of the interlobular connective tissue septa of the lungs which are infiltrated with serum. This serum, though it contains nothing visible, is nevertheless very virulent. And by culture in a small sac of collodion full of ordinary nutrient bouillon with a trace of lymph, incubated for fifteen days in the peritoneal cavity of a rabbit, along with a control culture of bouillon to which an equal amount of serum, which has been sterilized by heating to 55° C., has been added, one finds in the bouillon with the active lymph a slight suspiciousness, so slight that it would not have been perceptible without the control culture. Microscopic examination shows very fine, mobile granules which, after staining with thionin, appear, under the strongest possible magnification, slightly elongated. They are, however, so small that it is very difficult to pronounce on their form. After successive cultures, as described above, reinoculation produce the original disease. There is consequently here no question of a toxin, but of a self-producing virus. It is thus certain that the peripneumonia germ is a microbe at the limit of visibility. Later, it has been found possible to cultivate the microbe outside the body, at 38° in bouillon plus 6 to 8 per cent. of beef serum; and, by adding gelatin, to obtain colonies upon a solid medium. The colonies are stained with the anilins, and decolorized by Gram's method. Filtration through a Birkefeld filter renders solutions containing this microbe sterile, as tested by both culture methods, and inoculation.

In 1898 Sanarelli observed a disease in the laboratory rabbits, which consisted of a purulent discharge from the conjunctivæ, and the anal and genital orifices; and later, the formation of myxomatoid neoplasia. The virulent fluids (pus, blood, pulp of the organs) showed nothing under the microscope, and culture methods failed entirely, yet the fluids in question transmitted the disease.

These facts led Sanarelli to believe that here, too, we are dealing with an infra-visible microbe. The "mosaic" disease of the tobacco plant is another case in which nothing can be found, yet the fluids retain their virulence, even after filtration through the usual bacteria-proof filters. Again, the majority of the horses brought to Europe from South Africa suffer from a disease known as "horse sickness." The fact that horses properly sheltered at night are usually spared, suggests that perhaps infection may occur through some nocturnal insect. The symptoms consist of fever (with nocturnal remission), respiratory disturbances, and speedy death. At autopsy the lungs are found engorged with serum, which is virulent. The virulence is retained in spite of filtration (in one-thirtieth dilution), yet culture methods reveal nothing. A Chamberland F filter arrests the passage of the germ, as the filtrate is sterile. This shows that we are not dealing with a toxin which would, of course, pass through in solution. Altogether Roux's paper, while most interesting, is far from reassuring, as it shows that the catalogue of our foes is by no means complete.

## RECENT SEROTHERAPEUTIC PROGRESS.

IF the dreams of such men as Ehrlich, Brieger, Marmorek, Dunbar, Wright and others take tangible shape; if what may to-day seem to us the too-vague flights of their imaginations can be crystalized or conglomerated into practical therapeutic entities, there will be a profounder medical revolution in the coming century than was even dreamed

of by the great captains and masters of the past.

In a lecture on "Therapeutic Inoculations of Bacterial Vaccines," published in a recent issue of the *British Medical Journal*, A. E. Wright says: "The method which I propose to consider to-day is as yet almost unexploited. None the less does it seem to me to be one destined to revolutionize our ordinary practice in dealing with localized bacterial invasions. Our treatment in the past has consisted in making repeated applications of antiseptics, or, if impractical, extirpating the seat of infection. The time will come when, before embarking on either of these methods of treatment, an endeavor will be made in every case to arrest the invasion and to prevent its recurrence by calling into action the forces of resistance which lie latent in the organism. The physician of the future will, I foresee, take upon himself the rôle of an immunizator."

The declaration of such a creed in the leading article of the *British Medical Journal* is in itself enough to make one pause, only to realize an utter inability to grasp what a practical verification of these concepts may mean. For humanity, such a step in advance would inaugurate a blest passing of fully 95 per cent. of all bodily ills and pains. Death in childhood, in adolescence, in adult life, would occur only as the rarest exception.

For the medical and for the kindred professions which cluster about it, it would mean dissolution. One man with a case of phials from the municipal laboratory could minister to the great town which to-day absorbs the life energies of a score of physicians. The practitioners of medicine, the imposing drug stores, as well as the mighty corporations which manufacture pharmaceutical preparations—all would pass away.

What justification, if any, exists for believing us to be upon the threshold of such a medical upheaval; such a therapeutic revolution?

The success of Haffkine's antiplague vaccination has been second only to that attending the use of diphtheria antitoxin. Yersin's plague antitoxin, which differs from Haffkine's vaccine in being obtained from immunized horses, is curative as well as immunizing. Dunbar of Hamburg has prepared in like manner an antitoxin for the treatment of hay-fever, which "produced immediate disappearance of the subjective and, after a few minutes, great amelioration of the objective symptoms."

Nevertheless, there is no denying that the attempt to create "anti" sera to combat the common infectious diseases has, so far, largely failed. Some one has truly said that as a rule they contain "too much horse and too little 'anti,'" This, happily, is not so true of immunization efforts as of attempts to cure.

The results of the most recent experiments point, however, to a possible solution of the problem. They explain the cause of failure by assuming that the sera were prepared without fixed attention to what Wright calls the "law of the negative and positive phase and the attainment of the higher base line." The "negative phase" is that condition of depressed bactericidal power of the blood which follows the introduction into the system of a toxin. This is followed by the "positive phase," if conditions be favorable, and this, in turn, by a base line, which, in the absence of further inoculation, gradually returns to normal.

This law was probably first observed by Ehrlich. Madsen and Morgenroth subsequently took it into consideration in the preparation of their sera, but Wright believes that thus far the technique of applying the law has, in most cases, been faulty. He seems to have demonstrated the truth of this assertion by the success of his antistaphylococcus vaccine in the treatment of acne and furunculosis.

The reason why it has been so comparatively easy, with the crude methods at hand, to prepare efficient diphtheria antitoxin is that the negative phase is always of short duration and, most fortunately, corresponds very closely with unmistakable clinical symptoms. The abatement of these marks the elimination from the system of all negative-phase blood. Thus, an interpretation of the clinical symptoms may easily predict the establishment of the positive phase and a higher base line of immunity.

If it be true that a more careful application of this law—which, it has been shown in the case of all infections save diphtheria, must be made by observing bacterial, chemical, or phagocytic reactions rather than clinical symptoms—will give powerful anti-coli sera, the long-sought goal is not far off. If such infections as cholecystitis, appendicitis, cystitis, endometritis, and many others dependent upon bacillus coli invasion, can be combated by anti-coli vaccinations as successfully as Wright has treated staphylococcus infections occurring on the outer surface of the body, the hand of the surgeon will, indeed, be stayed.

In the light, then, of these most recent observations the preparation of an "anti" serum should be attempted by so gauging the quantity of vaccine given, and so determining its frequency of administration, that the negative phase may be limited in extent and duration; that the positive phase may be marked, and that the base line of immunity may be high and prolonged. The manifestations of this law should, in future, be watched with the utmost care, for it indicates the trend along which progress must be made. The success of therapeutic inoculation will, however, continue to depend, particularly from a curative rather than from a protective standpoint, upon the power of response of the individual.

When we shall have learned to choose in a given case between the introduction of a vaccine for the treatment of localized infections, and a serum prepared in strict accord with the law above quoted; when to a degree we shall understand the chemical reactions which elaborate the complex immunizing products; when we are able indefinitely to preserve unaltered these products after their withdrawal—then, indeed, distinct serotherapeutic advances will have been made. There are those who believe that this degree of knowledge is not far distant.

---

### The Mortality in the French Army.

The health of the French army is arousing great concern among persons of all classes in France. The mortality amongst French soldiers is abnormally large, and shows no signs of decreasing. In the *Revue de Paris*—according to the *Review of Reviews*—is an article by an anonymous writer, who plainly states the facts of the case, and discusses the question as to why the death rate is so much higher in the

French army than in the German. Typhoid fever during the past twenty-five years has been the bane of the French army, but recently tuberculosis has made fearful ravages amongst its ranks, owing, it is believed, to the increase of drunkenness throughout the nation. The chief reason given by the writer for the ill-health which pervades the French army is the insanitary accommodation provided for its members. Although every effort has been made to enlarge the army, little or no money has been expended in building barracks. The consequence is that "whole regiments of soldiers shiver in winter and perspire in summer, their dwelling any kind of old farm building near the regular barracks which the government is able to hire at small cost." Again, most of the barracks are defective in sanitation, and there are constantly occurring in military quarters terrible outbreaks of what are presumably water-borne diseases. There is only one feature of the German military system of which the French soldier has no need to be envious, that is the food. The feeding of the French troops is greatly superior to that of the German army. The army of which the French people are so proud would seem to be veritably draining the life blood from the nation.

### Further Experiments with Formalin.

Dr. Antonio Fanoni published in the *Post Graduate*, June, 1903, the result of some experiments he has been making upon rabbits with formalin. His object was to determine: (1) The efficiency of formalin solution 1:5000 in septicæmia. (2) Whether the favorable results claimed for formalin, 1:5000 in 0.7 per cent. saline solution are due to the formalin or to the so-called salt-solution. (3) What part the virulence of bacteria plays in septicæmia. His aim also has been (1) To test the efficiency of intravenous injections of formalin in anthrax and pneumococcus septicæmia. (2) To test the efficiency of so-called physiological saline injections, and to determine, if possible, whether or not the favorable results claimed for formalin should be attributed to the water. (3) To decide which solution was preferable. Being unable to secure a culture of streptococcus of sufficient virulence to kill rabbits, Dr. Fanoni was compelled to experiment with the anthrax bacillus and attenuated cultures of the pneumococcus of Frænkel. Although it is difficult to compare the results obtained upon animals with those which might be secured with human subjects, the conclusions reached as the results of experiments with intravascular injection of 1:5000 formalin upon rabbits, even in doses of 0.00031 to 0.00061 per 100 grams of body weight, convinced the writer that this method of treatment is not only useless, but actually dangerous in experimental septicæmia. Recovery, he thinks, is not due to the formalin, since the same results were obtained with simple saline solution, and no treatment, with the advantage of not exposing the animals to any danger during the first two or three days, at which time the organism should be strengthened and not weakened, and retain all of its resources in order to combat the disease. Recovery is due to the attenuated virulence of the pneumococcus.

"The virulence of the bacteria is also a grave factor in a case of sepsis," says the author. "Fortunately in practice, bacteria are very often attenuated, and in such instances recovery nearly always occurs. If, however, they are very virulent or are made so experimentally, death will be the result."

Dr. Fanoni thinks that the experiments carried out by him prove that the organism may recover from septicæmia as the result of its natural resistance provided the virulence of the bacteria is not as intense as that of the microbes used experimentally.

The results of his experiments upon rabbits with formalin and with saline solution are supported by four cases of septicæmia in man, reported by Dr. Park, all of whom "received from 500 to 750 c.c. of a 1:5000 solution of formalin, and all four of whom died in from five days to three weeks after injection with formalin solution."

Finally Dr. Fanoni states that upon the basis of his experiments, he would recommend in septicæmia and sapræmia fractional intravascular injection of so-called physiological saline solution (0.9 per cent.), which at present, he thinks, gives better clinical, as well as experimental, results than formalin solution of any strength.

### Tuberculosis in Childhood.

Prof. Clifford Allbutt enjoys a well-deserved reputation for profound knowledge of medicine. In addition to the medical lore which he has acquired he is endowed by nature with the genius of expressing himself both in speech and in writing with remarkable eloquence and lucidity. On November 6, 1902, he delivered an address on tuberculosis at Glasgow which was a model of its kind both in matter and in phraseology. Referring to tuberculosis in childhood he said, "An opinion has been held by physicians at home and abroad, physicians of the highest authority, that in most cases, perhaps in all, it is during childhood that tubercle establishes itself in the human frame. This opinion I would not propose to you too confidently; yet as a broad and effective aphorism, I believe it to be not unveracious, and if this be so, it points to a still more jealous care of our children. The passage of tubercle from parents to child is so rare as to be negligible; the disease is usually incurred during the years in which the child inhabits the floor, and inhales its dust. Again, the fungus may be taken in with the food, or by licking pencils and slates, by sucking dirty finger-nails, and so forth." Dr. Allbutt, although he has little hope of entirely preventing tuberculosis in childhood, at any rate for some time to come, thinks that when the fact is taken into consideration that inoculation of it in early life may often be the origin and source of an outbreak many years later, no work can be more important than the provision of sanatoriums for delicate children. He suggests that large cities should erect by the seashore a group of cheap dwellings on the "cottage" system, to which should be sent children of consumptive tendencies. Such a scheme would be inexpensive, and ought to give good results. The proposition seems to be an excellent one, and by no means difficult of execution. Sanatoriums for children are quite as important, if not more so, than those for adults, for the reason that in childhood the seeds of the disease can be more completely eradicated than in grown-up persons.

### Physical Qualifications for Tropical Residence.

It is of paramount importance that those who wish either to reside or to travel in the Tropics, should first ascertain whether they are physically fitted to bear the change of climate. A person to be able to live in health in a tropical land should be perfectly sound. In *Climate*, April, is an address delivered by Dr. Charles F. Harford of the British Church Missionary Society, in which he gives his views as to the physical qualifications for tropical residence. Some of his remarks are somewhat well-worn, while

others bear the mark of freshness, but all are interesting and valuable as coming from a man who has had a wide and long experience of tropical life. He says in part: "The liability which there is in tropical regions to disorders of the digestive system renders it imperative that the person going abroad should be free from bowel disorder, liver trouble, constipation, diarrhœa, or indigestion in any form, seeing that not only are bowel complaints exceedingly common, but malarial fever itself affects chiefly the organs of digestion. The teeth also should be in good order, and there should be no faddiness as to food. Freedom from any form of nervous derangement is the next point of importance, and any tendency to headache, insomnia, hysteria, insanity, depression, or fits should be carefully inquired into. Slight valvular disease of the heart with full compensation need not exclude, while chronic bronchitis in a slight form is likely to be better in a hot climate." As to age, the writer is of the opinion that between twenty-five and forty years is the most suitable period of life in which to go out to the Tropics. Referring to sex, Dr. Harford says: "It has usually been taken for granted that men will stand the changes of climate better than women, but experience does not prove this to be the case. It is also a strange fact, which may be only a coincidence, that I have known more men returning from a tropical climate with a breakdown of nervous system than women." Speaking of the kind of physique best calculated to resist the inroads of a tropical climate, the author thinks that the person of spare and wiry build is better adapted for the Tropics than the stout and full-blooded individual.

The writer's suggestions as to habits of life, diet, and exercise are of much the same nature as those of other authorities on the subject. Of course he gravely warns Europeans in the Tropics against excess in alcoholic beverages—in fact, he deems it the wisest course for white men in tropical countries to refrain entirely from strong drink. Dr. Harford concludes by pointing out that if a person physically ill-fitted to stand the unaccustomed strain put upon his constitution by the climate of the torrid zone goes out to take part in any undertaking in a tropical country, that it is not only the risk to the individual himself which has to be considered. Many such an undertaking has been demoralized, not only by failure of health on the part of the few, but from the fact that the more able-bodied have been obliged to spend their time in nursing the weaker members of the party.

### Treating General Puerperal Septicæmia by Intraabdominal Irrigation with Saline Solution.

Dr. James Hawley Burtenshaw recently read before the New York Polyclinic Society an account of a case of general puerperal septicæmia which came under his care, treated in the manner described above with successful results. The woman thus infected was in a very grave condition, and Dr. Burtenshaw resolved to irrigate the entire abdominal cavity thoroughly with saline solution as a last resort.

The methods of procedure were as follows: Several gallons of saline solution, prepared according to the formula of Locke, containing sodium chloride 3 iiss; calcium chloride, gr. 3¾, and potassium chloride, gr. iss to the quart of sterilized water, was prepared and kept at a temperature approximating 110° F. A four-quart fountain syringe and tube were sterilized by boiling. The patient was given a few whiffs of chloroform, and a two-inch incision was made into the abdominal cavity, midway between the umbilicus and pubes. A rubber pad was placed under her to catch the overflow, and the tube of the syringe was inserted through the opening as far as possible into the pelvis. For one hour the solution was permitted to flow into the cavity without intermission, and twenty minutes after the irrigation had been begun, ten ounces of urine of a specific gravity of 1,024 was obtained by catheter, and fifteen minutes later six ounces. At the end of an hour her temperature, which had been 104 F., had dropped to 102.6° F., her pulse rate, which had been 120, to 110; she was in a profuse perspiration, and her mental condition had greatly improved. At ten o'clock at night the irrigation was repeated for half an hour. A large quantity of urine had been collected. The bowels had moved freely twice, and her temperature and pulse rate had fallen in a satisfactory manner. A third irrigation was practised the following morning again for half an hour, and at three-hour intervals until ten o'clock the next morning, the cavity was filled with the saline solution. The next day the abdominal wound was closed with stitches, and the patient eventually made a complete recovery. Dr. Burtenshaw is of the opinion that the report of the above case is unique, on account of the length of time the irrigation was practised, the effect of the irrigation on the kidneys and peritoneum, and the ultimate recovery of the patient without the ordinary sequels of septic peritonitis.

---

### Medical Attendance in Department Stores.

When the summer shopping season is at its height in New York and in other large cities, it naturally often occurs that persons—principally women and children—who visit the hot and crowded department stores, are taken suddenly ill. As a rule, the individual is hurried into the street, or into the nearest druggist's store, where, if sufficiently ill, he or she must wait until an ambulance or physician appears. This involves much discomfort, and occasionally even more unpleasant consequences. The New York *Tribune*, June 29, describes a system now in vogue in many of the large department stores of New York, by means of which medical attendance or nursing aid may be obtained on the premises. These stores have sick rooms, suitably furnished and provided with the necessary equipment. A woman is in attendance who is supplied with a number of simple remedies, the use of which she understands.

In most of the large stores there is also a physician, either on the place or within easy reach, while a trained nurse is always kept on the premises. If the patient is not relieved by simple remedies, the trained nurse is sent for, and then, if dangerous symptoms supervene, the store physician is summoned. In a human hive, like a modern department store, where thousands are employed, and where thousands come and go during the day, facilities at hand for medical attendance are not only a necessity, but, as the writer in the *Tribune* says, "represent actual money-saving to the firm. Employees, who would lose a day's work if sent home, can frequently return to their duties after being treated in the physician's office. In case of an accident to employees or customers, the presence of a physician may not only prevent serious consequences which would follow delay in receiving medical aid, but insure a valuable witness in case of a damage suit."

It may be said that in most stores the physician's salary is paid by the firm and employees in conjunction, while he treats all employees free of charge.

### Plague and Fleas.

Simond's theory that fleas traveling from rats which have died from plague have frequently bitten human beings and thereby disseminated the disease, has up to the present met with little favor among those who have closely investigated the malady. Simond's view, as set forth in *Annales de l'Institut Pasteur*, Vol. XII, 1898, p. 628, is as follows: "The idea of transmission by means of a parasite, which would seem to be the conclusion drawn from clinical experience, is in accordance with the invasion of sick rats by fleas, which several hours after death abandon the cadavers to attack other animals and man." This is confirmed (1) by the presence of the specific microbe in the intestinal contents of the flea; (2) by other certain peculiarities of transmission from rat to man, and from man to man, in which latter case it is possible that other parasites, more particularly the bedbug, may intervene; (3) by the possibility of the transmission of plague to a healthy rat by his cohabitation with an infected rat with fleas, when such cohabitation of healthy rat and flealess infected rat is uniformly innocuous. The great stumbling-block to an acceptation of Simond's theory has been the assertion made by several authorities—and especially by Professor Galli Valerio—that fleas from rats will not bite human beings. Now, however, Dr. Frank Tidswell of Sydney, well known for his studies and reports on plague, has come forward with the statement that some of the fleas which infest rats will bite human beings. He writes thus in the *British Medical Journal*, June 27: "In opposition to Simond's hypothesis that bubonic plague is disseminated by fleas from infected rats, it has been urged that the fleas of rats will not bite human beings. Simond himself, whilst admitting his inability to pronounce upon the species of fleas found by him upon rats, nevertheless clearly states that they bit human beings upon whom they were placed. Prof. Galli Valerio of Lausanne has reported that the species of fleas found by him upon rats are Typhlopsylla musculi and Pulex fasciatus, and that neither of them will bite man. Simond's observations were made in India and Valerio's in Europe, and it seemed by no means improbable that their conflicting results were due to the fleas found by them being of different species. It does not follow that the fleas harbored by rats in two widely different places would be exclusively of the same species. With a view to determine this point a collection of fleas was made from the rats coming under my examination during the recent epidemic of plague at Sydney. Of 100 fleas obtained 10 were identified as Pulex fasciatus, 8 as Typhlopsylla musculi, 1 as Pulex serraticeps, and 81 as Pulex pallidus. It will be seen that no less than four species were represented, and most abundantly one (pallidus) not hitherto mentioned, as far as I am aware, as occurring on ordinary rats. Its stated hosts are Mus albipes of Socotra and Herpestes ichneumon of Egypt. This species bit in laboratory trials, as did also Pulex fasciatus upon one occasion. Pulex serraticeps is well known to attack man. The remaining species, Typhlopsylla musculi, did not bite us." Dr. Tidswell announces that an official report on the matter will be forthcoming soon, and remarks that in the meantime it may be noted that the results of his observations tend to remove an otherwise fatal objection to Simond's views.

## News of the Week.

**Roof-garden for Tuberculous Patients.**—Dr. Edward Martin, Director of Public Health and Charities of the City of Philadelphia, has had erected on the roof of the Philadelphia Hospital a capacious garden, 200 feet long by 30 feet wide, with accommodations for 100 tuberculous patients, who will spend all of their time there. The floor is well boarded, and a covering of heavy duck canvas affords protection against inclement weather.

**To Suppress the Toy-pistol.**—The Pennsylvania State Board of Health, in view of the number of deaths due to the toy-pistol, will recommend to the State Legislature the passing of an act surrounding the use of this dangerous weapon with suitable restrictions.

**A Graduate Prize at the Medico-Chirurgical College of Philadelphia.**—By the will of Spencer Morris, formerly professor of medical jurisprudence and toxicology, the sum of $12,500 is bequeathed to the Medico-Chirurgical College of Philadelphia, the income from which is to be awarded annually to the member of the graduating class who receives the highest general average at the final examinations for the degree of doctor of medicine.

**Association of Surgeons of the Southern Railway Co.**—This meeting was held at Fortess Monroe, Va., July 7, 8, and 9, under the Presidency of Dr. Rhett Goode of Mobile, Ala. The following officers were elected for the ensuing year: *President*, Dr. R. L. Payne of Norfolk, Va.; *First Vice-President*, Dr. J. S. Voyles of Corinth, Miss.; *Second Vice-President*, Dr C. P. Martin of Blockton, Ala.; *Secretary* and *Treasurer*, Dr. J. J. Harrison, Jr., of Loudon, Tenn. As honorary members were elected Drs. Floyd W. McRae of Atlanta, Ga., and E. Franklin Smith of New York. The next place of meeting will be Louisville, Ky.

**Bequests to Philadelphia Hospitals.**—By the adjudication of the will of the late Mary M. Johnson of Philadelphia bequests to the following hospitals become operative: Pennsylvania Hospital, $10,000; Insane Department of the Pennsylvania Hospital, $10,000; Asylum for the Relief of Persons Deprived of Their Reason, $10,000; Hospital of the University of Pennsylvania, $10,000; Woman's Hospital of Philadelphia, $10,000; Howard Hospital, $5,000; Pennsylvania Training School for Feeble-minded Children, $5,000; Orthopedic Hospital, $5,000; Philadelphia Home for Incurables, $2,000; Children's Seashore House, Atlantic City, $2,000.

**New Jersey State Dental Society.**—The annual meeting of this society was held at Asbury Park on July 15, 16, and 17. The election of officers resulted as follows: *President*, Dr. Herbert S. Sutphin of Newark; *Vice-President*, Dr. W. D. Chase of Princeton; *Secretary*, Dr. Charles A. Meeker of Newark; *Treasurer*, Dr. Henry A. Hull of New Brunswick. It was decided to hold the convention next year at Asbury Park.

**Medical Department of the University of Chicago.**—It is announced that Mr. John W. Rockefeller has expressed his approval of the various items contained in the $1,000,000 fund raised by the trustees of Rush Medical College as a condition to the admission of that institution to the University of Chicago. The approval of the fund means that the college will soon become an integral part of the university, that Mr. Rockefeller will make another donation of several million dollars; and that the college within a few years will have new buildings with a hospital attached.

**The New Jersey Consumptives' Home.**—It has been discovered that, although the New Jersey Legislature appropriated $300,000 for the erection of a State Home for Consumptives at Glen Gardner, no bill for the disbursement of this sum was passed, consequently the appropriation is not available. As a result of this omission, it has been necessary to stop work on the sanatorium and to wait until the Legislature meets again and a bill for the proper distribution of the money can be passed.

**Another Consumption Cure.**—The Chicago Board of Health, having shown that a drop of lemon-juice on an oyster will give a quietus to the typhoid bacilli in its stomach, has now issued a bulletin calling attention the anti-tuberculous serum of Maragliano of Genoa. This scientist, who resembles the traditional prophet to a certain extent, delivered an address before the Madrid International Congress, abstracted in our cabled report of May 2, in which he decried the sanatorium treatment of consumption and lauded the use of a so-called immunizing serum. There is nothing new in the preparation of anti-tuberculous sera. They were prepared and tried long before Maragliano's announcement, and have proved to be of little, if any, practical value. Tuberculosis is not a self-limited disease, nor is one who has been cured of the disease necessarily, or even usually, immune against future invasions of the tubercle bacillus. It would be a great calamity if the popular movement in favor of sanatoria should be arrested now by the preachments of the Maraglianos with their anti-tubercle serums.

**Dr. Henry L. Shively** of this city has been appointed visiting physician to St. Joseph's Hospital.

**Typhoid Fever at Ithaca.**—The newspapers have recently published reports that typhoid fever was again epidemic at Ithaca. These reports have been denied, but at the same time it is admitted that there are some cases in the city and that the public water supply is still liable to pollution. Dr. George A. Soper of the New York State Board of Health has made a statement that the total number of cases in Itacca on July 16 was nine, of which three were more than two weeks old, and that there were less than half a dozen suspicious cases under observation. The general health conditions of the city, he says, are satisfactory, "except for the water supply. The attention of the local Board of Health has been called to this subject, and energetic steps are now being taken to remove the sources of pollution." Those "energetic steps" should have been taken last spring, and the fact that they are only "now being taken," at the beginning of the season of typhold-fever prevalence, is not reassuring.

**A Strike of Hospital Nurses.**—Seventeen nurses at the Milwaukee, Wis., county hospital, the entire staff, went out on strike on July 17. They rebelled against the strict discipline enforced by the head nurse, and when the superintendent refused their demands for the discharge of the offender, the young women all left at once.

**The Plague in Chile.**—The United States Minister at Santiago de Chile has sent a cable dispatch to the State Department reporting a serious state of affairs in Chile in consequence of the rapid progress of bubonic plague in nearly all the seaport towns. He says that the plague, which it was thought was confined to a few places, is now spreading to nearly all ports. The alarm in Chile is so great that the postal service is disorganized, and only one American mail has been received at Santiago in nine weeks.

**A Dinner to Mr. Jonathan Hutchinson.**—A number of friends of Mr. Hutchinson gave him a complimentary dinner on Thursday of this week, which was the seventy-fifth anniversary of his birthday. The dinner was held at the Trocadero Restaurant, London, and in deference to the honored guest's views on the causation of leprosy it is understood that the usual fish course was omitted.

**The New York City Hospital for Consumptives.**—Mr. Homer Folks, Charity Commissioner of this city, recently presented to the board of estimate a report setting forth his views as how best to establish a hospital near the city for the treatment of consumptives. He says that the new hospital must have an elevation of from 600 to 1,000 feet, must be sufficiently remote from thickly settled regions to insure pure air, must be sheltered from northerly winds, have an abundant supply of good water and be accessible by rail. He recommended that the sanatorium be built to accommodate 500 patients, and that the buildings and grounds cover an area from 250 to 400 acres. It will not be necessary to construct many expensive buildings. Cheap wooden structures for some of the patients, and tent cottages, such as have been constructed at the Tuberculosis Infirmary on Blackwell's Island by this department, are inexpensive and are probably better suited to the needs of the patients, so far as dormitory purposes are concerned, than more expensive buildings. The cost of these tent cottages at Blackwell's Island, accommodating twelve patients each, is about $90 for materials and $30 for labor. Such a site as is desired, Mr. Folks says, could be secured for from $100 to $250 an acre. He estimates the yearly cost of the maintenance of 500 patients at $182,500.

**Care of Consumptives in the City.**—In a lecture delivered by Dr. S. A. Knopf before the Summer School in Philanthropic Work, conducted by the Charity Organization Society of the City of New York, July 17, 1903, a plea was made for increasing the open-air facilities for the poor suffering from tuberculosis. Two things, he said, could be done for the immediate relief of these sufferers: First, one or two recreation piers should be reserved exclusively for pulmonary invalids. There they could spend the greater part of the day; one or two nurses could be detailed to supervise them. At least a few hundred of the consumptive sufferers among the poor could thus be made comfortable. Another way of caring for the earlier cases of tuberculosis during the summer would be to take them on daily excursions on the river or sound. There they could be cared for in the same way as on the pier. The hospitals within the city limits, besides the two on the islands, which offer a number of their beds to consumptive sufferers, could also, Dr. Knopf said, increase the comfort of this class of patients during the hot weather by making the top of their buildings into roof-gardens suitable for the open-air cure and for sleeping quarters for the consumptives at night. On the top of nearly every hospital a roof-garden could be improvised by covering it with a canvas roof to which were attached side-flaps for use when protection from sun or rain was necessary. With a few flowers and a little shrubbery here and there, the place could be made very attractive and the whole system could be installed with relatively little expense.

**The Medical Uses of Radium.**—A despatch to *The Sun* quotes from an article in the London *Times* of July 18, dealing with the practical uses of which radium can be put. "Some of the most hopeful and most important uses of radium," the writer says, "are in the field of medicine. Physicists and doctors

complain of the impossibility of regulating the character of *x*-rays so as to repeat with certainty any desired result. Radium gives a beautifully consistent and uniform supply of rays. Instead of the cumbrous focus tube, nearly as large as a football, and the manifold expensive items of the *x*-ray outfit, a glass tube somewhat smaller than a toothpick and containing from one-tenth to one-fifth of a grain of radium, has already been successfully employed in cases of cancer, since the little tube can be inserted in cavities no larger than the nostril. In a great many cases in which it was impossible to use the *x*-rays, radium has been readily employed, as is shown by the following case at Charing Cross Hospital: A rodent cancer of the nose which had recurred after an operation and had been successfully treated by the *x*-rays, was subjected to a short exposure of radium. Four exposures, aggregating about an hour. were given at intervals of a few days. In three weeks the diseased part was healing well, and in six weeks, after two further exposures, the cancer disappeared completely without leaving any visible scar. Similar success in treating a cancer was reported from Vienna last week. The fact that radium inclosed in a lead box an inch thick and brought near a person in a dark room causes the same feeling as a flash of light on the retina, even when the eyelids are tightly closed, and that the same sensation is experienced by the blind, is attracting the serious attention of medical men, and the successful treatment of many other diseases than cancer may be confidently expected in the near future.

**Obituary Notes.**—Dr. EDWARD V. ARMSTRONG died in the Presbyterian Hospital in New York on July 16. He was thirty years of age, and was a retired assistant surgeon of the United States Navy. His death was due to a tropical fever he contracted while serving in the far East. When the Spanish war became inevitable, Dr. Armstrong offered his services, and was appointed an assistant surgeon on April 15, 1898. He served on the *Scorpion* during the war, and then went to the Philippines. There he contracted the fever, and was very sick, but recovered partly. His eyes were affected, and this caused his retirement from the navy. He returned here and never regained his strength.

Dr. A. E. ROGERS, assistant physician at the Bonner Springs, Kansas, Sanatorium, lost his life on July 16 in an attempt to save one of the patients in a fire which destroyed the building. Three of the patients were burned to death at the same time.

Dr. THOMAS M. ROCHESTER of Brooklyn died on July 12, at the home of his mother in Rochester, N. Y., of pulmonary tuberculosis. He was a great grandson of Col. Nathan Rochester, the founder of the city which was named after him. He was a graduate of the Medical Department of the University of Buffalo in 1878, but settled in Brooklyn soon after entering the profession, and practised there until compelled by the state of his health to retire, three years ago.

Dr. W. D. HAMILTON died at Kennett Square, Pa., on July 2, at the age of thirty-eight years. He was a graduate of Jefferson Medical College.

Dr. ISAAC N. F. BEEDLE of Ocean Grove, N. J., died of cardiac and renal disease on July 20 in Asbury Park, at the age of fifty-five years. He was graduated from the Bellevue Hospital Medical College in the class of 1870.

Dr. WILLIAM H. PARISH of Philadelphia died recently. He was a graduate of the Jefferson Medical College in the class of 1870, and was professor of anatomy at the Woman's Medical College of Pennsylvania.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

HISTORY OF MEDICINE; FITZPATRICK LECTURES—ANEURYSM—THE CARLYLE DISPUTE—NEW COLONY FOR EPILEPTICS—JENNER INSTITUTE—SUNDAY FUND—THE LATE WM. CADGE OF NORWICH

LONDON July 3, 1903.

THE first FitzPatrick Lectures have been duly delivered at the Royal College of Physicians. This lectureship was founded by the widow of the late Dr. FitzPatrick, and the "History of Medicine" was the subject chosen by Mrs. FitzPatrick as one in which her husband had been greatly interested. Dr. J. F. Payne delivered the first course, and having said that the "pious and generous gift" of the foundress deserved the cordial thanks of the college, already rendered, but also recognition from all who are interested in the progress of the two sciences, medicine and history. He further said the services of Dr. Norman Moore, who had been Mrs. FitzPatrick's adviser as to this scheme, deserved recognition, and added that he would have wished Dr. Moore to be the first lecturer, but he had decidedly declined.

Dr. Payne spoke of Dr. Norman Moore as "our eminent *Fellow*" and as an "intimate friend of our deceased *member*" This member he described as "a physician of great worth, learning, and accomplishments," but he expressed no surprise that such a physician had never been elected a Fellow. One would have supposed that Dr. Moore, who knew his "worth, learning, and accomplishments," would have reported them to his fellow-officials at the college. But then these are not precisely the qualifications for election to the Fellowship, and no doubt his intimate friend knew that Dr. FitzPatrick's modesty would never permit him to ask for admission to the self-elected inner circle. Curiously enough Dr. Payne, in commenting on the "lamentable apathy and little industry" of English physicians toward medical history, went on to say that in medical biography we have an unequalled work in the late Dr. Munk's Roll of the College. But that work, valuable as it is, by its nature excludes all practitioners who did not belong to the college, and it cannot be pretended that any one of the corporations embraced at any period the whole of the profession. Still the roll which was produced by the patient accumulation of the materials through many years before Dr. Munk was asked to print it is an important contribution containing all that he could ascertain about those who joined the college from its foundation in 1518 down to 1825. Though Dr. Payne lamented our apathy and perhaps exaggerated it a little, he did justice to continental productions and added that "our cousins across the Atlantic are now displaying characteristic energy and zeal in the study of the antiquities of medicine."

To return to the lectures, Dr. Payne began, so to say, at the beginning of the history, and it being impossible to extend his view over a long period confined himself to Anglo-Saxon medicine, dating its commencement from the introduction of Christianity by Augustine (A. D. 597), though it must be admitted that there are vestiges of earlier medical beliefs. It is to the schoolmen we must look for the few hints of anything like medical teaching. King Alfred evinced interest in medicine, and Helias of Jerusalem sent him certain prescriptions, including the Theriaca of Andromachus. Next came the "Leech Book," a sort of primitive manual of medicine, borrowed for the most part from the later Greek physicians as freely as our modern textbook writers copy from each other. I may say the same for the Herbaria which followed, especially as to the figures of plants which were copied by the compilers of the Anglo-Saxon MSS. With regard to native plants, of course the descriptions could not have been taken from Greek or Latin writers, and they show considerable knowledge of botany. These and other Anglo-Saxon books were referred to by Dr. Payne, who dealt particularly with the magical rites and charms described in them.

Passing by these, which the lecturer divided into seven classes and commented on each, we come to the later Anglo-Saxon books. One of these *Περὶ Διδάξεων* differs much from the others; it gives recipes which are collected from them and many others. It is also quite free from the charms and superstitions, and seems to be based on the writings of the school of Salerno. It belongs to the early part of the twelfth century and shows that the Anglo-Saxons were profiting by Salerno before that school came under the influence of the Arabian medicine. It also shows the continuance of Anglo-Saxon medicine long after the conquest, as does a MS. of the Herbarium of Apulieus of about the same period, and which closes the early English medical literature, as does the Anglo-

Saxon chronicle that of its general literature about the same time.

The treatment of aneurysm by subcutaneous injections of gelatin has not been extensively tried here. Some cases reported at the Medico-Chirurgical Society may therefore interest you. Dr. Guthrie Rankin related four which he had treated at the Dreadnought Hospital, using a two-per-cent. solution. The average number of injections was seventeen. In three out of the four cases there was a diminution of the pressure on surrounding tissues, which was probably the cause of the relief to the symptoms obtained. The after-histories showed the beneficial results to be permanent. Dr. Rankin considers the injections given with proper precautions to be safe, and that they alleviate all the subjective and many of the objective symptoms.

Dr. Robert Maguire said he had treated eight cases, seven of them with improvement. In one an aortic regurgitant murmur disappeared after the third injection, showing it was due to stretching of the aorta, not valvular disease. Another case which seemed about to burst externally was greatly relieved. One of the cases succumbed to tetanus, the spores of which are commonly present in commercial gelatin, which should, therefore, always be boiled for ten minutes. Dr. Maguire mentioned the risk of clot-formation in other arteries if they were diseased. He attributed the rise of temperature to the introduction of a foreign proteid into the circulation.

Dr. F. H. Hawkins said there were other risks besides tetanus. In one case in which he had tried the treatment, it was followed by a rigor with collapse and persistent vomiting for three days.

Dr. A. J. Whiting asked how soon symptoms of tetanus followed the injection in Dr. Maguire's case, and whether the coagulability of the gelatin was impaired by the boiling. To this Dr. Maguire said one week elapsed from the first injection before the onset of tetanus. Boiling did not alter the coagulability of gelatin.

Dr. Rankin, in reply, said he had met with no symptoms to cause anxiety.

Another paper on aneuyrsm was communicated to the same meeting. This was by Mr. D'Arcy Power and Mr. G. H. Colt, and consisted of a case of abdominal aneurysm in a man of twenty-nine years, who had previously been treated by five injections of gelatin without benefit. The sac was very thin—life seemed in peril and an operation was decided on—the artery to be tried if practicable, and if not the sac to be filled with silver wire. The sac was exposed but could not be isolated, and eighty inches of silver wire were introduced by means of an ingenious instrument, devised and made by Mr. Colt. It only took two and one-half minutes to introduce the wire. The patient seemed comfortable next day, but the pulse kept rising and he died fifty hours after the operation. The post-mortem showed that the aneurysm sprang from the aorta just below the diaphragm. The sac was full of recently clotted blood entangled in the wire. On cutting across the aorta seven inches of wire were found projecting upward into the arch. A patch of adherent pericardium was the only other abnormality.

The Carlyle controversy continues with unabated virulence. In the new *Contemporary*, Sir J. Crichton-Browne returns to the subject in order to reply to Mr. Ronald M'Neill's article in the June number, but as his reply was in the editor's hands before the publication of Froude's apologia he announces that later on "a full, and it is hoped final, answer, will be given." He declares it would "be criminal to allow Froude's hideous and bedaubed portrait of Carlyle to go down to posterity as in any degree authentic." That Froude disregarded Carlyle's injunctions as to his own papers is practically admitted in his apologia. But what is worse, is the publication of Mrs. Carlyle's love letters. This betrayal of trust has been condemned in all directions, and Sir J. Crichton-Browne remarks on the horror with which Mrs. Carlyle would have felt at their being canvassed by the million. "And not only the love-letters but the journal containing the most secret communings of Mrs. Carlyle's spirit in her hours of solitude, which she had kept under lock and key from Carlyle himself." But enough of this dispute—if you think more than enough for a medical journal, consider that it is occupying columns of newspapers, pages of magazines, and intruding into nearly all medical or literary conversations. Even the legal journals find an excuse for referring to it in warning disputants that slanders of dead persons are misdemeanors, and that the surviving relatives, who are pained by the comments which cannot be justified as properly historical, may bring an action in the courts. I hope the warning may not be without effect on those who maintain that the public—"the many-headed beast," as Tennyson called it—has a right to pry into the private affairs of every dead distinguished writer.

The Princess Louise, accompanied by the Duke of Fife, opened the new colony for epileptics of the County Council. The Asylums Committee of the council determined in 1898 to establish this colony, and has erected the buildings on the Ewell estate of the council, utilizing above 100 acres of the estate for the purpose, in a very beautiful locality. In the center is the administrative block, and dotted about the grounds are eight pretty villas, each arranged to accommodate thirty-eight patients. Great attention has been paid in the designs to secure for the inmates plenty of freedom and yet to be under supervision. Around each villa is a garden, which the colonists will cultivate. There will also be cricket and other sports, dining hall, recreation rooms and, in fact, everything desirable for such an institution. At present, provision is made for 266 men and 60 women. The cost has reached £98,000.

Death by misadventure was the verdict of a coroner's jury on Wednesday, in a case in which a man went into a chemist's shop for a dose of morphine, to which he was addicted, and was given strychnine instead.

Besides the birthday new honors I mentioned, there were several promotions. Thus Dr. P. Manson, who was C.M.G. becomes K.C.M.G. Surgeons-General Colvin Smith and Cole Reade, in the same way, from C.B. pass to K.C.B. Surgeons-General G. J. H. Evatt and A. Scott Reid were given the C.B.

The Jenner Institute of Preventive Medicine will henceforth omit the name of Jenner and revert to its former title, British. This has become necessary on account of a manufacturer of calf lymph having long before called his establishment the Jenner Institute. The money subscribed to the Jenner Memorial will probably be used to found a scholarship. Dr. C. J. Martin, F.R.S., has been appointed the new director of the institute. He is professor at Melbourne University.

Up to the present time only a little over £40,000 has been received for the Hospital Sunday Fund—a sad record of the wet and cold June.

Yesterday Messrs. Butlin, Makins, and Dent were elected to the vacancies in the council of the Royal College of Surgeons. Mr. Butlin's was a re-election.

"Cadge of Norwich" died on the 25th ult. You will recognize him by this title, for I hear he was as well known by this name on your side of the Atlantic as on ours. He was in his eighty-first year and had for a long time retired from practice. But his works follow him, and among them may be put forward the rebuilding of the Norwich Hospital, in which he had won his world-wide reputation, and to which he devoted munificent sums during his life. You will know him best as the great authority on stone in the bladder, for his world-wide reputation as to that branch quite overshadowed his skill in other departments of surgery. It seems like ancient history to think of his presence at the first operation under anæsthesia in this country, of his election on the staff of University College Hospital, and then throwing up a London career for one in his native city, and with which his name will always be associated. In 1874 he gave the address in surgery at the British Medical Association. In 1886 he delivered the Hunterian Lectures at the Royal College of Surgeons, in which he embodied his ripe experience as an operator for stone.

**A Rare Case of Staphylococcomycosis in Diabetes Mellitus.**—The connection between the presence of sugar in the urine and affections of the skin was noticed long ago. On one hand the incontrovertible fact has been established that those suffering from sugar exhaustion are much more subject to affections of the skin than those suffering from other diseases, that the organism of a diabetic offers much less resistance to the entrance and development of pus-producing bacteria; on the other hand, it has been observed that certain affections of the skin may occasionally call forth the appearance of sugar in the urine. In the first case the connection of cause and effect is, to some extent, proved by the observations of Professor Bujwid, who found that the staphylococcus thrives best in a medium containing sugar, and that the tissues in the presence of sugar cannot resist the action of this microorganism. J. B. Studzinsky describes a case under his observation. In a patient suffering from diabetes mellitus, an apparently pustular eruption appeared upon the extremities. The pustules kept growing, and upon reaching the size of a dime broke down, followed by the formation of granulation-tissue, and proliferation of the surrounding epithelium. Cultures of staphylococci were obtained from the affected areas, so that the diagnosis of cancer had to be excluded, in spite of the marked proliferation of the surrounding epithelium.—*Russkii Vratch.*

**Subparietal Injuries of the Kidney.**—Francis S. Watson reports his own cases, six in number, with results of the treatment. The most striking features in the analysis of the clinical data are the high death rate attending the expectant treatment, as compared with any form of operative intervention, and the conspicuously low mortality of the series of cases treated by operations other than nephrectomy. The expectant treatment shows at its worst in the cases with intraperitoneal complications. The low mortality in the series treated by operations other than nephrectomy, compared with that attending the latter, is obviously due to the fact that the operation which was selected instead of nephrectomy—lumbar incision and suture, tamponing and drainage, or nephrectomy, etc.—was chosen for the reason that the kidney was not found to be so seriously damaged as to require nephrectomy. In other words, the cases were of a less grave nature. Hemorrhage is the one factor which most often demands prompt operative treatment. The writer appends a series of nephrectomies, 1,118 in number. The deaths from these were 301; mortality, 26.9 per cent. The total number of lumbar operations was 722; recoveries, 557; deaths, 165; mortality, 22.9 per cent. The number of abdominal operations was 365; recoveries, 234; deaths, 131; mortality, 35.6 per cent.

*Journal of the American Medical Association, July 18, 1903.*

**A Study of the Histological Changes in Epithelioma under the X-ray.**—J. C. Stewart reviews the theories previously presented in reference to the effect of the *x*-rays on superficial malignant growths, and gives the clinical history of a cancer of the wrist following an injury. Portions of the excised tissue were submitted to the usual manipulations and a study of them (illustrated in his paper) leads him to offer the following conclusions: (1) It is probable that when epitheliomata react favorably to *x*-ray treatment that characteristic histologic changes will be found. (2) The important early changes are fatty degeneration and vascularization of the epithelial pearls. (3) Leucocytic infiltration and various degeneration processes complete the destruction. (4) Bodies indistinguishable from "Plimmer's bodies" multiply as epithelia degenerate.

**Clinical Diagnosis of Intestinal Parasites.**—C. W. Stiles dwells on the absolute necessity of examining the fæces in order to arrive at a positive diagnosis of intestinal parasites. Such examination must be made with the microscope, for mere gross examination does not suffice. An increased eosinophilia is an indication of possible parasitic infection, and such a result from blood examination should make us suspicious. The blotting-paper test is reliable in about 70 per cent. of cases. It is made by allowing several ounces of the stool to be wrapped up in the paper. In severe and very median cases it will be noted that a reddish-brown stain appears on the paper. The technique of microscopical examination is described. The author states that the biologic principle on which fecal examination rests is that the eggs of different animals are more or less characteristic. Accordingly, to carry out properly the examination one must become familiar with the eggs and embryos of different species, also with the form of certain plant cells and fibers which might be mistaken by the uninitiated for eggs or embryos of parasitic worms.

**Sunshine and Fresh Air vs. the Ultraviolet Rays and the Röntgen Rays in Tuberculosis of the Bones and Joints.**—Dr. Forest Willard presents the following conclusions: (1) Sunlight, fresh air, and good food, together with fixation and protection of the affected joint, are the most important agents in the contest with tuberculous infection. (2) Direct exposure to the rays of the sun is essential, and all hospitals should be provided with solaria or sun porches and roof gardens. (3) Patients lying in bed should have the diseased joints exposed to the direct rays of the sun, their heads and eyes being protected by green glasses or shades. The joints may be covered with blue, so as to secure easiest passage of the ultraviolet actinic rays, and local medications rich in iodin may be also employed as desired. (4) Tent life on the hospital grounds, or better, in the open pine forest, can be successfully employed through both summer and winter. (5) Sanatoria should be established for tuberculosis of the hard tissues, as well as of the soft. (6) The concentration of the sun's rays by lenses is of positive benefit in bactericidal influence. As final curative agents, however, the direct sun's rays are most effective. Electrical rays can be used when sunlight is lacking. (7) The Röntgen rays in the laboratory have an inhibitory power on the tubercle bacilli, and may prove useful in restraining the growth of these microorganisms in living tissues. (8) The actinic rays and the *x*-rays are both apparently helpful in the fight with tuberculosis, but several years will be required to determine accurately their effect. They should be employed not to supersede, but to antedate and to supplement operative procedures, to assist the mechanical protection of the joint, and to increase the general therapeutic measures employed.

*Medical News, July 18, 1903.*

**The Daily Rhythm of Epilepsy and Its Interpretation.**—L. Pierce Clark summarizes his paper as follows: This study of 150,000 seizures shows that there is a more or less definite daily rhythm in the epilepsies, in the early morning, which roughly divides the twenty-four hours of the day into eight-hour periods. There are also smaller or secondary rhythms. The interpretation of the rhythm is explained on the basis of cerebral fatigue and the accumulation of waste products at these periods which produce auto-intoxication, and, which, in turn, exhibits itself in seizures during light sleep and during the day, when the loss of cerebral inhibition is greatest. Secondary and contributing factors are: manner of living, diet, exercise, occupation, sedatives, and the character of the epilepsy.

**Therapeutic Suggestions in Diphtheria.**—Louis Fischer declares that the specific treatment of a case infected with diphtheria consists first and foremost in giving it the required dose of antitoxin. The dose depends upon the severity of the disease. In laryngeal stenosis, in all 4,500 units can be injected during the first twenty-four hours. The treatment must be based on scientific data, hence it should conform with the result of what is found by culture from the throat and by the thorough examination of the blood. The streptococcus sometimes present, in addition to the Klebs-Loeffler infection, bronchopneumonia, nephritis, arthritis, otitis, and local abscesses are often present, due to the streptococcus. As a tissue and blood builder, no medication equals food. Milk, concentrated broths, and acid fruits are well borne. Older children can take raw scraped steak, calf's foot jelly, and ice cream. When rectal feeding is necessary, no more than two ounces should be injected at one time; milk, predigested, one ounce, starch water, one ounce, laudanum, one minim, can be injected slowly through a colon tube, after both colon and rectum have been cleansed by a soap-suds enema. If this enema is retained, the yolk of a raw egg may be added to it. The putrid membranes and the catarrhal discharges should be removed from the nose and throat. Fresh air is most important in the treatment of this disease. In fever it is well not to use antipyretic drugs. Sponging with alcohol and water or acetic ether, locally, is better. Cold packs and flushing the bowel with cold water are serviceable in some cases. The bowels should be kept clear. Stimulation should begin early. Strychnine, whiskey, tokay wine, champagne, coffee, caffeine, citrate, and sparteine may be used.

*New York Medical Journal, July 18, 1903.*

**A Case of Black, Hairy Tongue.**—The patient of R. H. Johnston was a man of fifty-six years in good general health, complaining of a peculiar sticking sensation in the mouth, and a blackness of the tongue. The trouble had existed for two months. Protrusion of the tongue showed a black discoloration almost round, measuring about 10 mm. in both diameters. It was located in the median line in front of the circumvallate papillæ, and was seen to be covered with hairs about half an inch long. These were removed with forceps, and under the microscope were found to consist of hornified epithelium, one cell on another. There was no swelling of the filiform papillæ. The mass of hair could be moved about on the tongue with a probe. The patient passed from observation and the later history is not known. The cause of this condition has never been accurately ascertained. Only about thirty-five cases are on record. The present case is the eighth reported in America. A bibliography of the literature of the subject is appended.

**Subconjunctival Medication, with Special Reference to the Use of Salt-sugar Solution in Acute Affections of the Anterior Portion of the Eye.**—H. McI. Morton states that in very acute affections of the anterior ocular chamber he has used the several mercury salts, but has more recently found that the injection of a large amount—say two to six grams—of sterile water alone, brings about a more speedy resolution of the inflammation and is less painful than the chemical agent. Still more recently he has used a three-per-cent. solution of sugar in normal salt-solution in corneal ulceration, acute uveitis, simple iritis (followed by the usual mydriatic), etc. The fluid is introduced by an ordinary hypodermic syringe, the capacity of which is just 1 c.c., and is injected so that it fills the subconjunctival space about the corneal margin entirely. This necessitates the introduction of

the syringe at several points just anterior to the insertion of the recti. In sthenic individuals where one eye alone is involved, the introduction of a large amount of fluid subconjunctivally is very properly an office procedure, but to be followed by slight pressure from Liebricht's pad, and the patient directed to use hot fomentations for periods of five minutes, with half-hour intervals. Bad effects from the injections have never been noticed.

**Artificial Immunity in Experimental Tuberculosis.**—E. L. Trudeau has succeeded in producing a relative immunity in rabbits and guinea-pigs against tuberculosis, though in his experiments thus far it has always been possible by flooding the systems of the animals with a large dose of highly virulent bacilli to produce death. The writer declares, however, that this is an unnecessarily trying test, and is in no way comparable to exposure to natural sources of infection. A typical experiment on a guinea-pig is thus described: On June 10, 1902, the animals to be protected received in the left thigh an injection of one-quarter milligram of attenuated T. B. R. 1 culture. Slight loss of weight followed, and on September 26 they failed to react to ten milligrams of tuberculin. They then received one milligram of living attentuated tubercle bacilli in the peritoneal cavity, which produced little appreciable disturbance of health. On January 7, 1903, they, together with five controls, received an injection of one-half of a milligram of highly virulent tubercle bacilli culture subcutaneously in the right thigh. The controls all died, with an average life of fifty-five days. The vaccinated animals survived, and now, one hundred and fifteen days after virulent inoculation, are in good condition. Some show at present no trace whatever of virulent inoculation, though some undoubtedly have chronic tuberculosis, as they have enlarged inguinal nodes. He has known such animals to live over a year. Further questions suggested by results obtained are these: What are the dangers of the immunizing process? What is the duration of the immunity produced? Is a living but attenuated germ necessary to the protective process? Can the immunity it produces be strengthened or not by additional inoculations of the toxins of the bacillus or of the serum of already immunized animals? Can the young be protected by the milk of immunized cows? Can the serum of protected animals produce immunity of shorter or longer duration and favorably influence the course of the disease in tuberculous men or animals? To all these questions no positive answer can as yet be given. The article should be read in the original by all physicians specially interested in the tuberculosis question.

*American Medicine, July* 18, 1903.

**The Etiology of Leukæmia.**—John Benjamin Nichols concludes that: Heredity, traumatism, and precedent disease conditions in a few cases may have some causative influence, but are of no more than subsidiary etiological moment. Almost nothing is known as to the specific primary cause of leukæmia. Aside from a nervous origin of the disease which has been suggested, the possible explanations seem to be limited to three. That it is due to a vice in the internal processes of cell life and division that comes into generalized activity, and results in exaggerated leucocytic hyperplasia; that it is the result of the action of toxic substances, autogenous or exogenous, generated at some unknown place in some unknown way; and, that it is of infectious or parasitic origin, the parasites acting by the production of toxins or otherwise. Of these only the infectious theory has been at all subjected to direct investigation. In the failure of proof of the infectiousness of leukæmia, the explanation of its causation would appear to lie between the toxic and the hyperplastic theory, with the probabilities, perhaps, in favor of the former.

**Diseases of the Gall-bladder and Bile-ducts.**—C. A. Ewald says that bacterial infection is not confined to the inflammation of the wall of the gall-bladder, with its consequences. It may also be followed by the formation of gallstones. Of the invading germs, B. coli communis is most frequently found. The reason for the stagnation of bile and the subsequent bacterial invasion is not truly known, and perhaps we must always consider predisposition. The gall-bladder at times becomes enlarged, either because of increased fluid or of obturation of the ducts by a catarrhal swelling of the mucosa, or both, which condition causes pain. Colic may be due to contraction because of the presence of stone, or to inflammation. For the diagnosis of gallstones there have always been three symptoms: colic, icterus, and tumor. The different kidney diseases attended by attacks of colic are easily recognized through a careful examination of the urine. A hyperleucocytosis speaks for a suppurative appendicitis and against gall-bladder disease. Empyema of the gall-bladder has no hyperleucocytosis. There are primary diseases of the stomach and pancreas which point rather to disease of the gall-bladder, and, conversely, there are diseases of the gall-bladder with secondary manifestations in the stomach and pancreas that obscure the primary condition. Under such circumstances the chemical examination of the stomach contents is very important. We must differentiate between gall-bladder colic and most cases of acute and chronic pancreatic disease. Jaundice may be the result of a mechanical obstruction or of functional disturbance. Tumor of the gall-bladder is more often absent than present. Finally, the complications of a cholecystitis and a new growth have to be considered. As to therapy, the internal treatment of cholelithiasis is very uncertain. The writer adopts the following measures: During the acute inflammatory stage and during colic he uses the known means for relief, and he advises, besides, lavage of the stomach with hot water or with a solution of nitrate of silver (Ehrlich), or the drinking of large quantities of hot water; in a severe acute infection, immediate operation; patients with rapidly recurrent favorable attacks he would rather treat internally, as the stones are probably of small size and able to pass. After such attacks the bile flows freely and the infection subsides. In unfavorable cases, with recurrent attacks, he advises operation, especially when stones lie in the ductus hepaticus or choledochus. Preventive means against recurrence should always be used.

*The Lancet, July* 11, 1903.

**The Uses of Sodium Salicylate in the Treatment of Malarial Fever.**—A. D. Kennard calls attention to the value of this drug in malaria. He believes that it reduces the temperature just as quickly as does quinine, and is of the greatest value in relieving the pains in the limbs of the fever sufferer. It will sometimes break the attack when quinine fails. The weak points in the writer's reasoning, are, first, that in the three cases reported he used the salicylate in connection with the quinine, though the two were not used simultaneously, and, second, that as the cases occurred on shipboard, he was not able to confirm his diagnosis of malaria by an examination of the blood.

**Arsenical Idiosyncrasy.**—John Phillips reports the case of a woman who was taking a tonic preparation containing, among other ingredients, one thirty-second of a grain of anhydrous arseniate of sodium. This dose, after three administrations, led to violent vomiting and a condition of severe acute irritant poisoning. It was necessary to give strychnine hypodermically, brandy internally, to apply hot bottles and poultices to the abdomen. Subsequently a saline infusion was given per rectum. Castor oil by the mouth and a hypodermic injection of morphine to arrest the retching and pain, followed at a later period by frequent doses of dialyzed iron, were given, and she ultimately made a good recovery. The interesting point in the case is that the total amount of arsenate of sodium was *less than one-tenth of a grain*, and this amount had been given in three separate doses with an interval of some hours between each dose, yet this minute quantity was sufficient to cause such alarming symptoms.

**The Treatment of Aneurysm by Subcutaneous Injection of Gelatin.**—Guthrie Rankin reviews the literature of this subject, and adds the clinical histories of four personal cases, all successful. In his judgment the cases show: (1) that gelatin injections may, with proper precautions, be given subcutaneously with safety; (2) that they produced a marked and speedy decrease in all the subjective and in some of the objective symptoms presented by internal aneurysms; (3) that this relief of symptoms is only explainable on the theory of a diminution in pressure-effects from shrinkage in size of the aneurysmal sac; (4) that this diminution in size, accompanied with marked increase in the resistancy of the tumor wall, was capable of physical demonstrations in three of the cases treated; and (5) that the after-histories of the patients, so far as they could be obtained, afforded evidence that probably the beneficial results were permanent—that, at least, they had not been seriously invalidated by the habits and exertions of the patients between the date of their discharge and that of their being last seen.

**Smallpox in the Fœtus.**—A. Warner reports two cases. The first case was that of a woman who aborted with twin female fœtuses at the fifth month. She had a very short time before passed through an attack of smallpox. Both of the fœtuses were covered with a well-marked eruption, distributed chiefly on the back, the head, and the neck, less on the abdomen and limbs, and there were two spots on the sole of one foot. The eruption consisted of yellow, circular patches with a central depression, the size of the majority of the patches being equal to the thirty-second part of a square inch. In the second case the patient aborted during her attack of the disease, the fœtus being three months old but showing no eruption. The author,

however, includes the case in his paper for the following reasons: First, there is the great difficulty in making the diagnosis in so young a fœtus; second, the mother had been successfully vaccinated in infancy, and therefore had no natural immunity to vaccinia; third, her primary vaccination could not have protected her up to the time of her illness (thirty-nine years), and fourth, while at the time of the miscarriage she had only the primary symptoms of smallpox, every other individual in the house where she was had the disease. It seems reasonable, therefore, says he, to suggest that her immunity to vaccinia (she had been unsuccessfully vaccinated during her sickness) was created by an abortive attack of smallpox modified by the fœtus.

*British Medical Journal, July* 11, 1903.

**A Case of Prolapsus Uteri Treated by Paraffin Injections.**—John J. Douglas and William Gream Stone describe this case. The patient was sixty-nine years old, and too feeble for a radical operation. The prolapsus was complete. Pessaries were useless. Injections of paraffin were made in several places under the mucous membrane of the lateral and posterior vaginal walls, and about the cervix. A finger was kept in the rectum for a guide, and a probe passed into the urethra. The lumen of the vagina has been very much narrowed, and its walls stiffened. The uterus is now completely held up during walking and defecation. The patient has no discomfort.

**The Necessity of Shortening Large Nerves When Amputating.**—Walter G. Spencer reports several cases which illustrate the necessity of drawing out the large nerves from the surface of the stump and cutting off a piece from them. When this procedure has been omitted, there has been an indefinite delay to the patient's recovery. The patient has been hindered from wearing an artificial limb and from returning to work. There has been continuous pain in the stump, and after several minor operations, at last a resection of the affected nerves has had to be resorted to. Amputation is done nowadays only as a last resource, and the patient's condition is generally bad. Therefore, haste is essential, yet the minute or two required for shortening large nerves is indispensable.

**A Case of Ascites Most Probably Caused by Infective Thrombosis of the Hepatic Veins.**—Henry Waldo reports this case. The patient was a married woman of forty-seven years. A few months ago she had cellulitis of one arm. Incisions revealed no pus. The arm was completely restored. Some months later ascites developed with pain and tenderness in both iliac regions. The ascites increased and interfered with breathing. The ankles were slightly swollen. By a process of exclusion, the diagnosis was narrowed down to infective thrombosis of the hepatic veins. There was no likelihood of syphilis. By rest and elaterium, and by inducing profuse diaphoresis and diuresis, the patient recovered in three or four months. It is possible that the climacteric was intimately connected with the fous atorigo mali.

**The Value of Lumbar Puncture in General Practice.**—Herbert Rhodes sums up some of the advantages of lumbar puncture. For the patient, it relieves pain and headache, diminishes coma, while consciousness may return after coma has been established through the increase of intracerebral pressure; it may indicate the necessity or otherwise for operation; it has been a definite aid toward recovery. For the physician, it may correct or confirm a diagnosis, by rendering less intense a coma from excessive intracranial pressure; it obviates the necessity of nasal feeding, and other such tedious and often dangerous, nursing procedures. The operation is practically without risk, as long as it is carefully performed and rigid asepsis ensured. It is rarely at all painful. There are almost always some good results.

**Brachial Neuralgia.**—Robert M. Simon states that neuralgic pains affecting some of the branches of the brachial plexus are sufficiently common in aneurysm, cancerous growths in the thorax or axilla, and in aortic disease; but brachial neuralgia not symptomatic of these causes is a rare condition, and one of such extremely painful nature as to demand more than the very prefunctory attention it has received. It is questionable if the term "neuralgia" is a proper one to employ, for the majority of these cases are not cases of neuralgia, but rather of perineuritis and secondary pain. It is quite possible that a depressed condition of health may predispose to the occurrence of brachial neuralgia, but some violence is always necessary to its development. The writer then reports several cases in which the patients suffered from pain in the arm along the distribution of the brachial plexus. He does not think that they justify the diagnosis of brachial neuralgia, for they were clearly traumatic in origin, and associated with definite pressure upon the branches of the brachial plexus. The other cases seen by the writer were similar in origin and symptomatology, and not due to neuralgia dependent upon constitutional condition. In all of his cases there has been a history of injury.

*Deutsche medicinische Wochenschrift, June* 18, 1903.

**Further Researches Regarding Streptococci.**—Hans Aronson has again taken up the subject of the unity or multiplicity of the so-called species of streptococci. He has taken streptococci from various sources (fifteen in all), including scarlet fever, puerperal septicæmia, otitis media, rheumatism, etc., and submitted them to agglutination and immunization tests. It is thus found that between all of these species there exist inter-agglutination and inter-immunization reactions. Since these are the most refined biological tests known it must be assumed, as the result of their application, that there is no such thing as multiplicity of species of streptococci, and hence, that they all come under one genesis. It can hence be affirmed that there is no such thing as a specific scarlet-fever serum which has been obtained from the inoculations of streptococci. These results in no way, however, negative the endeavor to produce a multivalent antistreptococcus serum similarly as other multivalent serums have been obtained, and it is feasible to suppose that such a polyvalent serum would be more efficient against streptococcus infection than any of the univalent sera which have hitherto been used.

**Kidney Death, Kidney Insufficiency, and Functional Kidney Research.**—Leopold Casper defends his methods of functional kidney research (phloridzin injections, etc.), against Israel's recent attacks. There can be no doubt but that these methods give precise information regarding the condition and functional activity of the kidneys, and that this is valuable information in those cases in which it may be thought advisable to a unilateral nephrectomy or nephrotomy. In such instances the subsequent outcome of the case depends in a large measure upon the condition and functional activity of the kidney which is not to be operated upon. For, if this is not sufficient to sustain life, such an operation is contraindicated unless the life of the patient is immediately threatened. An examination of Israel's kidney operations previous to 1901 shows that, in many instances, the condition of the kidney not operated upon was not understood, and that hence life was shortened instead of prolonged by the operation. If, in the eighty cases reported by him since that time, the results have been better it can only be ascribed to improved methods of examination used by him. What these methods are he does not state, although he says that "methods" have been used. Whether such methods are superior to those used by Casper it is not possible to say, but it is certain that the methods of the latter give an accurate diagnosis, and if put in operation will reduce the mortality attending kidney operations.

*Deutsche medicinische Wochenschrift, June* 25, 1903.

**Dissemination of Typhoid Fever by the Means of Butter.**—Carl Bruck, by experimental researches, shows that when butter is made from milk infected with typhoid bacilli, the bacilli pass from the milk into the cream and thence into the butter, where their presence may be demonstrated. It is thus apparent that butter is one of the chief factors in the indirect transmission of typhoid fever. The experiments were divided into three series: In the first series, pure cultures of typhoid bacilli were added to the milk from which the butter was made. In the second series, the milk cans were washed out with water which had been infected with typhoid bacilli. They were then filled with the uninfected milk from which the butter was to be made. After a short time the cream was centrifuged from this milk and butter made therefrom. The third series were identical with the second, except that the water used to wash out the cans was infected with the stools of a typhoid-fever patient, in which stools typhoid bacilli had been previously found. In every series the result was positive, typhoid bacilli being isolated from the butter.

**Symbiosis of the Influenza-bacillus.**—M. Neisser points out the fact that between the influenza-bacillus and the xerose bacillus there takes place a true symbiotic growth which is markedly to the favor of the first-named organism, so that in such symbiotic growth it can be easily cultivated upon the ordinary culture media without the addition of any hæmoglobin whatsoever. This fact was discovered by the author accidentally while "plating out" some of the fluid of a conjunctivitis accompanying measles. Colonies developed on the plates and these colonies were made up of both influenza and xerose bacilli. Transplantations were made, and it was found possible to continue this symbiotic growth through twenty generations. When the influenza bacilli were isolated from this symbiotic growth and inoculated on to ordinary culture media, they at once assumed their well-known characteristics and refused to

grow, except in the presence of hæmoglobin. These results were confirmed by experimenting with influenza bacilli obtained from other sources, in every instance the results being positive as above described. It was also found that a symbiotic growth takes place between the influenza and diphtheria bacilli, but such growth is not nearly so pronounced as that first described. It is thought as the result of the above, that a method may be developed which shall render more simple than hitherto the isolation of influenza bacilli, and also that further experimentation with the symbiotic growth of other organisms which refuse to grow, or grow only very slowly upon our ordinary culture media, may develop simpler methods for their isolation and growth.

*Berliner klinische Wochenschrift, June 29, 1903.*

**An Additional Case of Unilateral Compression of the Ureter.**—A. Steyrer reports another case. The compression of the right ureter due to tuberculosis of the right kidney and ureter. The urine from the right ureter was three times as great in amount as that from the left. The specific gravity and freezing point of that from the right side were 1008 and 0.69° C., while the corresponding figures of that from the left side were 1019 and 1.32° C. respectively. Tubercle bacilli were found in the urine from the right side. The case is cited in support of Ribbert's view, which has been confirmed by his own observations, as well as those of Bujniewicz and Strauss that a reabsorption takes place in the kidneys under certain conditions.

**Fatal Cachexias Without Anatomical Lesions.**—E. Grawitz reports a case which simulates others that frequently come under observation. The clinical picture is that of a progressive and fatal cachexia without apparent cause, and in which careful examination fails to reveal malignant growths. Addison's disease, pernicious anæmia, or any organic lesions. At autopsy nothing is found which throws any light upon the condition, and no satisfactory cause of death can be assigned. Such a case is here reported. The side lesion present during life was the absence of free hydrochloric or lactic acid in the stomach, and it is thought that this anacidity may be the etiological factor sought. Upon theoretical grounds such an acidity might give rise to an autointoxication, productive of a cachexia in either of two ways: (1) As its result the bactericidal action of the gastric juice fails, and microorganisms which are introduced into the stomach might thrive and produce toxins which slowly but progressively poison the system. (2) Because of the want of acids the metabolism of the albuminoids might be interfered with, so that the usual end products would not be formed, but in their place poisonous intermediate products arise. In practice both of these factors might be simultaneously operative. The fact that many healthy persons bear gastric anacidity with apparent impunity does not prove that in other healthy persons such anacidity might not give rise to a progressive cachexia, for it is a well-known fact that many individuals bear with impunity want of functional activity in various organs. Furthermore, it has frequently been observed that in various diseases (notably phthisis) the patient remains in fairly good condition until gastric anacidity develops, when they promptly show a marked cachectic condition, which usually runs a fatal course. It cannot, therefore, be doubted that in certain individuals gastric anacidity is the chief etiological factor in the development of a cachexia. This is further proven by the results of treatment in such persons, for if measures directed toward the gastric condition are instituted, and as the result free hydrochloric and lactic appear in the stomach, the cachexia usually promptly disappears. It is not intended to assert that the obscure class of cases here considered always appear in connection with gastric anacidity, but to point out the fact that at least in some of them this is the case, and to invite further observations along this line.

**Etiology and Specific Therapy of Hay-fever.**—Dunbar reviews the history of hay-fever and his previous experiments with the various pollens. Many clinical facts show that this disease is to be in no way considered as a nervous coryza, as has been thought by many. In susceptible persons it occurs only at a specified time of the year, even invariably beginning on a definite day. This fact alone differentiates it from all other known forms of coryza, and definitely proves that some other cause than the neurotic must be assigned for its development. Experimental research with the pollens has shown that a toxin may be extracted therefrom which is evidently albuminoid in nature, and which, when instilled in minute quantities into the eyes of persons susceptible to hay-fever regularly produces the characteristic symptoms of this disease. There are also other substances contained in the pollens, which may be extracted therefrom, and which possess the properties of an enzyme, but these are not at all specific, and when instilled as above never produce the symptoms of hay-fever. By the successive inoculations of the pollen-toxin into horses it has been found possible to produce a serum in them which when added in vitro to the toxin will absolutely neutralize it. Furthermore it will dispel the symptoms arising from the instillation of the toxin into the eyes of susceptible persons. The amount of the serum necessary to do this varies directly with the period of time which is allowed to elapse between the instillation of the toxin and the application of the serum. If this period is very short, one or two drops of an efficient serum cause an almost immediate disappearance of all the subjective symptoms. If, however, the period is long and chemosis has appeared, the frequent application of the serum becomes necessary. The author's experience with the serum has been thus far entirely experimental—that is, he has treated no ordinary cases of hay-fever therewith, but has only used it in laboratory experiments in which the symptoms alleviated were produced by the instillation of pollen toxin. Others have, however, used it in ordinary attacks of hay-fever with marked success, and the clinical evidence of its utility is daily increasing. It has been proposed to use the serum hypodermically instead of locally, and it is behind that so used it will dispel the symptoms produced by the instillation of the toxin. Its hypodermic use is, however, attended by disagreeable symptoms (swelling, etc.) at the site of inoculation, and hence at present the local instillation is to be regarded as preferable. Further research, it is hoped, may result in the production of a serum which gives rise to no irritation at the site of inoculation.

*French and Italian Journals.*

**Dermoid Cyst of the Nose.**—W. Dubreuilh reports a case in a child of seven years. According to Lannelongue and Menard, dermoid cysts of the nose are primarily congenital fistulæ which become cysts only by temporary obliteration of their orifice. They admit, however, that they are formed by the inclusion of the ectoderm in the dorsal groove. The diagnosis of nasal dermoid cysts is not difficult. They are characterized by their orifice, from which they project hairs, and from which there is always a whitish exudate formed of corneal cells easily recognized by a microscopic examination. Extirpation is the only treatment. It is sometimes difficult on account of adhesion of the cyst to the skin; in the author's case there was inclusion within the bone without adhesion.—*Journal de Médecine de Bordeaux*, June 28, 1903.

**The Anti-pertussis Serum of Leuriaux.**—Victor Jacques reports a number of cases in which injections of this serum were made to overcome the attacks of coughing in pertussis. In nearly all of them the attacks were reduced after five or six days to one or two in twenty-four hours, following one injection of the serum. Not only the number but the intensity of the coughing spells were diminished. In cases treated from the onset, recovery appeared complete in from ten to fifteen days. In a few cases in which the action of the remedy appeared to be slow, a second injection was administered. The serum does not induce a rise of temperature as a rule; if any occur it is slight. Five times out of twenty-eight cases, urticaria followed the injection, but the pertussis was cured nevertheless. The serum does not increase the number of white corpuscles.—*Bulletin de la Société Royale des Sciences Médicales et Naturelles de Bruxelles*, May, 1903.

**Chloroform in the Treatment of Tænia.**—Celestino Carratù holds that chloroform is the best medicament in the case of tænia because of its easy administration and its certain posology; because it is perfectly tolerated and is absolutely innocuous, so that if necessary it can be repeated within two or three days. Its efficacy is equal to that of any other remedy, it is inexpensive and simple to use, because the patient does not have to undergo any form of preliminary treatment. The dosage is six grams of chloroform to sixty of simple syrup, taken fasting in three or four doses of a teaspoonful each every hour and a half, followed by a purgative dose of castor oil about an hour after the last dose of chloroform. This is the maximum amount needed; sometimes three or four grams will be sufficient, and the intervals between doses may be two hours.—*Giornale Medico del Regio Esercito*, Vol. LI, Nos. 3, 4, 5, 1903.

**The Hysterical Eye.**—M. A. Trousseau states that in cases in which it is difficult to decide whether the patient is suffering from a cerebral or medullary lesion, or merely from a traumatic neurosis, an examination of the eye frequently clears the diagnosis. Hysterical amblyopia is frequent; it is characterized by a weakening of central vision, which does not go below ½ to ⅓; the visual field while contracting preserves its normal form, and there is perversion of the color sense which is subject to definite laws. The power to see colors disappears in the following

order: violet, green, red, orange, yellow. Blue is the last to go. When the disease improves, blue reappears first, then yellow, orange, red, and finally violet. This form of amblyopia is absolutely characteristic of hysteria, since it is found in no other affection. If hemianæsthesia exist, there may be anæsthesia of the palpebral and bulbar conjunctiva, and even of the cornea. More or less marked photophobia, attacks of ophthalmic migraine, pains in the pupil, orbit, and back of the neck while working are often the accompaniments of hysteria. There may be contractures of the intrinsic and extrinsic muscles. Trophic or vascular troubles consist in œdema, sweating, hemorrhages or ecchymoses of the eyelids, chromidrosis or a blue coloration of the integument, or more rarely ecchymoses of the conjunctiva, hypersecretion of tears, or even tears of blood if a conjunctival hemorrhage coexist with lacrymation.—*Le Bulletin Médical*, June 27, 1903.

**Splenomegaly in Acquired Syphilis.**—Nicola Sorrentino concludes, from his investigations, that during the primary period of infection the spleen as a rule remains normal. It is only during the latter part of the second period of incubation, or during the manifestation of prodromal symptoms, or during the period of involvement of the lymphatic glands or of the skin, that the spleen becomes appreciable. Splenomegaly in syphilitic infection is the manifestation of infection of the whole organism, and has therefore the same clinical significance as general involvement of the lymphatic glands. It is almost a constant manifestation of the first months of the second stage. As the disease progresses, the enlargement of the spleen diminishes, this being due to the attenuation brought about by time and by special treatment. The almost constant presence of enlarged spleen in the first part of the second stage may serve as a means of diagnosis when other symptoms are lacking.—*Giornale Internasionale delle Scienze Mediche*, June 30, 1903.

*The American Journal of the Medical Sciences, July*, 1903.

**The Lymphatic System and the Tonsils.**—Henry L. Swain believes that the practical deduction from his study of this subject is not to give free rein to indiscriminate attempts at removal of tonsils first, second, or third, nor is it to let them alone. The practical point is in operating, to be thorough, and that to remember when it is done, we have some tonsillar tissue left. Immunity is not conferred by operation, only less liability to infection and disease. There is a broad field for progressive work along the lines of strengthening the bulwarks which nature has erected.

**A Xiphosternal Crunching Sound.**—Myer Solis-Cohen has observed this sound in six patients out of 492 cases, or one and one-fifth per cent. This sound is superficial, and may be compared to the sound of a boot treading on soft snow. It is heard over the lower end of the sternum and a little to the left of it. The exact area varies, as well as the intensity, and occasionally slightly, the position, but never the character. It is not influenced by exercise, respiration or pressure. In every case the heart was enlarged and the cardiac sounds were weak and of poor quality. Retraction of the interspaces was noted in three cases. The pulse averaged about 82. The blood count was normal, practically, the hæmoglobin about 85 per cent. The sputum was negative. The cause of this sound can only be conjectured till more work has been done on the subject.

**Hiccough, Report of a Case.**—L. W. Atlee, after discussing the etiology of hiccough, states that owing to the great variety of conditions which may give rise to hiccough, the treatment found successful, has been of the most extreme diversity. When a case proves rebellious to remedies directed only to the correction of the apparent cause of the hiccough, resort may be had to medicines of a purely antispasmodic character. Chloral is the most effective, and should be given in full dose. When gastric irritation is largely the factor in its production, counterirritation to the epigastrium is of the greatest benefit. The diet should be very simple. Violent emotion has been known to stop hiccough. When it is due to sudden large losses of fluid from the body by hemorrhage, or in Asiatic cholera, it is relieved by its restitution through the introduction of normal saline solution.

**The Indications for Operative Intervention in Middle-ear Suppuration.**—Barton H. Potts reviews the symptoms indicating operation in many cases of chronic suppurative otitis media: Profuse and long-continued discharge is suggestive, but not diagnostic, of antrum or mastoid involvement. The fluctuating swelling over the mastoid is diagnostic when present, but its absence does not contraindicate operation. Œdema behind the auricle is more apt to be due to furuncle. Tenderness over the mastoid, especially in the region of the antrum, is of great significance whenever present, especially if it is persistent; but this may be doubtful or absent if the outer table is much sclerosed. The inflamed, tender, and bulging upper and posterior canal wall, is one of the most important signs of all, and its non-relief by treatment is a sure indication for operation. A sinus, whatever its location, leading into the mastoid is a positive indication. Facial palsy is of interest, but not important. Epileptiform attacks are unusual, but indicate possible cerebral pressure. Marked and rapid failure of health is more apt to be found in adults than in children. The temperature is more apt to be elevated in children than in adults. The rapid fluctuation of temperature through a range of several degrees is the most important sign in cases of pyæmia. The slow and steady pulse, out of proportion to the elevation of temperature, irregularity or sluggishness of pupils, rapid failure of health, rigors or convulsions, are signs of intracranial pressure. Tenderness and œdema over the occipital are very apt to be present when the sinus is thrombosed. Bacteriological examinations are not positive, but important.

**Histological Character and Diagnosis of Malignant Neoplasms of the Digestive Organs and Peritoneum.**—John G. Hemmeter declares that it is a characteristic of malignant tumors that cells of other types than the original are never involved in the growth. In the diagnosis, first the anatomical properties should be considered; second, the topographical; third, the distribution of the various tissue types in the tumor, and fourth, the properties and peculiarities of the cells. The most reliable criterion of malignancy is the metastases. In examining sections of neoplasms of the gastrointestinal tract, the muscularis mucosæ is, as a rule, an important landmark. Any proliferation of epithelial cells around a gastric ulcer, for instance, which has extended downward along the peptic ducts and broken through the "muscularis mucosæ," the writer is in the habit of considering malignant. The most difficult histological diagnosis of stomach tumors has been encountered in deciding between chronic hyperplastic gastritis and scirrhus. The proliferation of the great majority of cancers in the digestive tract starts from the surface, cylindrical, or columnar epithelium, or from the gland cell. All observations of mitosis have reliable value only when made on faultless material. All malignant tumors show an especial tendency toward disintegration, and especially cancers, which are situated on the surface, almost always form ulcers. Although the diagnosis of the two forms of tumors, cancers and sarcomas can be formed with tolerable certainty, the malignancy of complex tumors is exceedingly uncertain, and only to be diagnosed from the anatomical picture when its malignancy has already become manifest, that is, when real metastases have been developed. It is well known that the human gastric or peptic ulcer may become transformed into an adenocarcinoma apparently spontaneously. A structural characteristic of the adenocarcinoma which has developed on the basis of a gastric ulcer consists in an oblique ascension of the fibers of the true muscular layer, and a descension of the fibers of the muscularis mucosæ, the fibers of both muscular layers converging toward and fusing into each other in front of the edge of the ulcer, which is here composed mainly of connective tissue. A section made perpendicular to the surface of the stomach, and through the entire bed of the ulcer, almost invariably exhibits the general outline of a fish-hook. The writer believes that we are justified in concluding that any gastric adenocarcinoma presenting these striking features, has been developed on the basis of a pre-existing gastric ulcer.

---

**Why Minor Gynecological Operations Fail to Give Anticipated Results.**—Sigmund Goldberg first defines a minor gynecological operation as one which does not involve the opening of the peritoneal cavity. To be of any permanent benefit, he says, it must be performed within at least one year from time of the infliction of the original lesion. After the passage of about a year, either Alexander's operation, trachelorrhaphy, or curettage, or all combined, will be insufficient to restore the patient to perfect health. The reason for such failure in the great majority of such cases, after one year, is that the adnexa are sure to be involved. The best course will be to do some operative procedure intraabdominally, and not by the internal inguinal ring puncture of Goldspohn, but by free incision, so that the exact condition can be ascertained and properly treated, and this the author holds to be the proper procedure, rather than to depend upon the uncertainty of physical palpation.—*Buffalo Medical Journal.*

of the palate, deduced from the examination of many dead skulls; and to Alkan's work of a similar nature from measurements of living subjects; and commented on the peculiarities of the relation of shape of skull to palatal arch, in different races; and noted also, that upon examination of many children with and without adenoids (or other nasal obstruction) the former were found to have uniformly a higher arched palate than the latter; and noted also that anomalies in the position of first or deciduous teeth are frequent in those having deformities of the palate, and may be due to the latter condition. Dr. Swain found that in Flathead Indians, who deformed, by depression of vertex, the heads of their children, the arch of palate was very low (though the septum was not affected), showing that outside influences tending to alter the shape of the skull can and do affect the palate. He said that deformities of the arch were due, not to any *one*, but to many and complex factors. The nose, in these cases, is usually a non-functionating organ; in the new-born babe the level of palate is above that of the eustachian tube; at puberty below it, and, consequently, the palate has grown down, away from the base of the skull, this being due to the downward growth of the superior maxilla, the septum and the pterygoid process of the sphenoid bone. From improper, or no functional activity of the nose, this downward growth may be stopped; and, perhaps, because the nasal obstruction prevents the proper aeration of the maxillary sciences, the lack of air causing non-development or atrophy. The author also called attention to the added weight of the cheeks and inferior maxilla, dragging on the outer part of the superior maxilla when the mouth was constantly open and relaxed, thus tending to pull the sides together and narrow the arch. He also noted the dental fact that the shape of the adult palate, as well as the alignment of the permanent teeth, depends largely upon the preservation of the first or milk teeth as long as possible. When noting the great results in adults of the comparatively slight force used by dentists in straightening teeth and spreading them apart, Dr. Swain thought it reasonable to grant that the forces mentioned in his paper, when acting upon young, soft, and pliant bones, might easily be sufficient to cause the deformities found in these cases. Summarizing his paper, the author noted particularly: (1) That outside artificial deforming forces acting on the skull may alter the palate. (2) That when such forces do act on the skull and palate, the septum seems to accommodate itself to the altered conditions. (3) When the superior maxilla fails to descend, a bent septum is likely to result, just as it is when the palate is much narrowed and so arched up laterally. (4) Importance of lack of proper aeration of maxillary sinuses due to nasal obstruction. (5) Importance of preservation of first or deciduous teeth as long as possible.

Dr. DELAVAN of New York commended Dr. Swain's paper, especially for its calling attention again to the old idea of the importance of the first teeth, and of nasal obstruction; the moral being that attention, and early attention, should be given to those two things in every young child.

Dr. BROWN of Toronto, speaking of the examination of skulls, said that of many which he had examined he found only 50 per cent. normal or approximately so.

Dr. MAYER of New York said that he thought the reason that the teeth seemed to have such influence upon the shape of the palate was on account of their weight. That is, the borders of the maxillary bone are the heaviest parts, and when the weight of the teeth is added to them, the combined weight would surely be an important factor in influencing the shape of the palate.

Dr. MAKNEN of Philadelphia called attention to the great importance of nasal breathing, and referred to the estimate made by some observers, that 70 per cent. of all people breathe through the mouth at night, even when there is no obstruction to nasal breathing.

Dr. SIMPSON of New York asked Dr. Swain if he had noticed any influence upon the palate from nursing or from the constant use of a rubber nipple, when not actually nursing. He also referred to the habit of mouth-breathing during active exertion. Mouth-breathing at night not due to nasal obstruction he thought due to position, viz., lying upon the back.

Dr. KING of New Orleans said that while he had not made any definite measurements in the negro, he had observed that deformities of the palate and adenoids were not so frequent as in whites. That adenoids, when present, were not often associated with palatal deformities; and that the palate, as a rule, was larger, and the postnasal space more roomy; and so, when adenoids were present, they did not cause so much obstruction.

Dr. Swain, in closing the discussion, said that he had not observed any influence of nursing, or the use of the artificial nipple upon the growth of the palate. In reference to the negroes, he thought that, as negroes usually have such good teeth, perhaps their first teeth last longer and thus help in the production of a normal palate.

**Acquired Cicatricial Deformities in the Respiratory Tract, Due to Other Causes than Syphilis and Traumatism.**—Dr. G. HUDSON MAKUEN of Philadelphia read this paper. He said that deformities of this character were rare. He had sent a circular letter to 300 laryngologists, asking for information and data, and had received notes of 447 cases, in only 167 of which, however, was a definite cause assignable with certainty. Of these 16 per cent. were due to diphtheria, 8 per cent. to scarlatina, 3 per cent. to lupus, 1.6 per cent. to tuberculosis, 1.5 per cent. to a combination of scarlatina and diphtheria, 1.1 per cent. to typhoid fever, and .5 per cent. to measles. The author gave histories of two cases of his own, and argued that, in these common acute infectious diseases, more care and attention should be given to the throat and nose.

Dr. FARLOW of Boston said, in discussion, that while diphtheria might cause moderate adhesions between the tonsil and the pillars of the fauces, or between the pillars and the posterior pharyngeal wall, he did not believe that it could cause very extensive adhesions or contractions. He had never seen such a case. He thought that in many of those cases the history was defective, and that the cause was probably syphilis.

Dr. MAYER of New York noted that the cases were all in this country; that typhus was a common cause of such conditions, and was a common disease in some foreign countries, and very rare in this country. He thought if foreign statistics were included, that the number of cases would appear much greater.

Dr. THEISEN of Albany reported two cases of laryngeal cicatricial stenosis, one following typhoid fever, and one following a severe attack of influenza.

Dr. BROWN of Toronto reported one case of tuberculous origin.

In connection with the following papers on sinus disease, Dr. GEO. B. WOOD of Philadelphia gave, by invitation of the council, an exhibition of head sections of a six-months old child which were beautifully made and mounted, and were of special interest in showing the size and location of the accessory sinuses in a child of that age.

**Improvements in the Radical Treatment of Chronic Suppurations of the Accessory Cavities of the Nose.**—Dr. H. LUC of Paris read this paper. He considered, in order, the maxillary, frontal, ethmoid, and sphenoid sinuses.

I. Maxillary Sinus.—He stated first that radical surgical treatment was to be strictly limited to the chronic forms. He noted the distinction to be made between two classes of cases; first, the properly so-called sinusitis, with a primary infection of its mucous membrane; and second, cases in which the pus does not originate in the sinus, but merely accumulates there, coming from a frontal or dental abscess. In latter cases washing out may effect definite cure, in connection with proper treatment of the source

(frontal or dental inflammation). In former class of cases, puncture and washing should be tried first, and if unsuccessful, should be followed by operation. As to operation Dr. Luc advised an extensive bony resection—first of the anterior wall of antrum making a temporary opening into mouth; and second of internal lateral (or nasal) wall to make a permanent opening into nose, the latter including the ablation of the greater part of the inferior and middle turbinated bones.

II. Frontal Sinus.—Dr. Luc referred to the Ogston-Luc operation, and spoke of the frequent poor results from it, in cases of very large sinuses, due to the closing of the nasal drainage opening before the cavity of the sinus is healed up. This unpleasant result had caused many to go back to old method of leaving the wound open, or to use the Kuhnt operation of resection of whole of the anterior wall, with its consequent great deformity. Dr. Luc recommended and now uses the Killian operation, a combination of the Ogston-Luc with the Kuhnt and Jansen operations, getting the immediate closure of the wound and nasal drainage of the Ogston-Luc; the opening in floor of sinus of Jansen's; and the removal of a part of the anterior wall of Kuhnt's method; but preserving a bony bridge between the two openings, which reduces the deformity, and extending the inferior bony opening to the ascending part of the maxillary bone, giving opportunity to enlarge the fronto-nasal opening, and also giving access to the ethmoid cells. Dr. Luc recommended this for cases of large sinus and the Ogston-Luc for cases of small sinus.

III. Ethmoid Cells.—These, the author said, were practically never involved alone, but always in connection with frontal or maxillary suppuration. They may be attacked through the nose, or as a sequel to operation on frontal or maxillary sinus. Dr. Luc stated that it was impossible completely to destroy the ethmoid labyrinth through the nose, as the *anterior* cells cannot be reached without making an external bony opening. But may do a good deal intranasally as a preliminary step to further operation from without. Dr. Luc had abandoned all nasal curettes as too small and weak, and used a special type of forceps, large and strong and flattened to pass readily into the narrow middle meatus. For the intranasal part of the operation the author advised first clearing out any myxomatous tissue in middle meatus; then removal of the middle turbinated; then attack with his curette-forceps upon the ethmoid cells, this being done under cocaine and adrenalin. Externally he recommended the Killian, or the Caldwell-Luc operation. In one case, intranasally, he opened into the sphenoid sinus, but this did no harm, and suggested a direct method of attacking that sinus, as he has done since then.

IV. Sphenoid Sinus.—Here Dr. Luc said that we could operate by intranasal route, or by external method through the maxillary sinus—always the former if the sphenoid sinus alone is affected and there is room in the nose—(or if not room, if we can make room); the latter if the maxillary sinus is also affected, or if we cannot get room in the nose in which to work. If only the middle turbinated bone and the ethmoid cells are in the way, remove them and enter sphenoid sinus through ethmoid region, as mentioned in speaking of ethmoid operation. The author noted that it was important to remove a large part of the anterior wall of the sinus.

**Diseases and Treatment of the Sphenoidal Cells, with Report of Case.**—Dr. ROBERT C. MYLES of New York read this paper. He first showed a number of instruments, made with a projecting flange or shoulder as a safety device, for operations on sphenoidal and ethmoid cells, and also some special forceps. He called special attention to the frequent irregularities and anomalies of size and position of the sphenoidal cells, and showed a very fine wet specimen, with sphenopalatine and internal carotid arteries injected, the former crossing the field of operation, the latter lying close against the very thin inner wall of the sinus. Dr. Myles said that he considered disease of the sphenoid cells much more common than usually reported. He advised the removal of posterior end of middle turbinated, when necessary, as a diagnostic measure; and when diagnosis is made advised making a free opening in anterior-superior wall of the sinus, 10 to 15 mm. in diameter, and close to the septum. Dr. Myles reported several cases, in one of which there was violent secondary hemorrhage nine and fifteen days after operation; from which case Dr. Myles thought that all these cases thus operated upon should remain under close observation for at least three weeks after operation.

**Observations on the Diagnosis of Nasal Sinusitis.**—Dr. WALTER J. FREEMAN of Philadelphia read this paper. He noted the frequent failure of the transillumination test for disease of the maxillary sinus, and called attention to the fact that when only one antrum was affected it was usually on the narrower or more obstructed side of the nose. In regard to the frontal sinus, he mentioned the usual train of symptoms, but gave special weight to the appearance of pus in the upper angle of the vestibule, claiming, that when persistent, this was practically pathognomonic. In inflammations o maxillary sinus, acute or chronic, the author considered pus flowing over the upper surface of posterior end of inferior turbinated as the surest and most frequent sign. He also claimed that an intermittent cacosmia was a frequent and valuable sign. If any of the molar or bicuspid teeth were capped, or were at all discolored, they should be very carefully examined. The author claimed to be able to wash out the maxillary antrum in most cases through the natural opening, and showed a slender, hard rubber cannula for that purpose. As to ethmoid disease, he expressed great skepticism as to the frequency of its occurrence, and the number of cases reported, and thought that most of them were undiscovered cases of antrum, frontal or sphenoidal suppuration. As to the sphenoid sinus, the author seemed to think that, excepting by process of exclusion, or by opening the sinus by an external operation, a definite diagnosis was impracticable or impossible.

Dr. BRYAN of Washington, in discussion of papers on the sinuses, spoke of the frequent anomalies, and showed a specimen, in which the sphenoid sinus was very large, and extended far down into the pterygoid process of sphenoid bone. He also expressed disapproval of the maxillary route for operation on sphenoid sinus.

Dr. MAYER of New York claimed that it was very seldom that the maxillary sinus could be washed out through the natural opening, but that it must be punctured—a very simple matter. He thought the antrum route to the sphenoid sinus was the best one, and would be *the* operation of the future.

Dr. HARRIS of New York spoke of the use of the Ogston-Luc, and the Killian operations, and strongly commended the latter. He also spoke of the puncture of the antrum as a routine procedure for diagnostic purposes as well as to wash out the sinus.

Dr. KING of New Orleans said that for most cases he considered the Caldwell-Luc operation the best for frontal sinus cases, but spoke of the occasional recurrence, due to closure of the nasal drainage opening, before the complete healing of the sinus cavity. He objected to the Kuhnt operation, on account of the great deformity resulting therefrom. He reported one or two cases done by the Kuhnt-Luc combination operation, with good results, and called attention to the frequent temporary infraorbital neuralgia following the Caldwell-Luc operation.

Dr. GLEITSMANN of New York spoke of a case of secondary hemorrhage, apropos of Dr. Myles' case, and said that he used liquid vaselin to loosen up the packing in all cases, thereby he thought lessening the tendency to hemorrhage. He also spoke of the distance to which

an instrument must be passed into the anterior nares in order to reach the sphenoidal sinus or its posterior wall. He found it very variable, in some cases 3½ to 4 inches, in others 5½ to 5¾ inches. He also mentioned the fact that in acute cases the anterior wall was not eroded, but in chronic cases it usually was eroded.

Dr. BRYAN of Washington asked Dr. Luc if he had found that the wound, *i. e.* the opening made between the maxillary sinus and the sphenoidal sinus, tended to close.

Dr. LUC, replied that he had not noted that fact especially, but felt that it did not. He said that he had not found any great difficulty in working through the floor of the frontal sinus. That the object of the operation was to obliterate the cavity of the sinus, and that often it was a choice between complete success in that point, and a considerable degree of deformity—as, *e. g.* in the Killian or Kuhnt operation. But if necessary, we must choose the latter. He said that the uprising of the fatty tissue of the orbit through the wound in the floor of the sinus (roof of orbit) helped to obliterate the cavity and reduce the deformity. As to drainage opening into the nose, it must be large enough to allow the finger to go *up* through the nose into the cavity of the sinus. He had not observed any cases of neuralgia, as noted by Dr. King, but had seen a number of cases of anæsthesia of a small area.

**Complete Removal of Left Vocal Cord for Malignant Disease; Presentation of the Patient.**—Dr. WALTER F. CHAPPELL of New York reported a case as described in above title. In January, 1901, the larynx was much infiltrated, with a small red growth on anterior end of left cord. In October, 1901, the case was operated upon, with tracheotomy, and thyrotomy, and total removal of left vocal cord and immediately adjacent infiltrated tissue. There was good recovery, and there has been no recurrence to date. The author urged early diagnosis and early operation by thyrotomy with radical removal.

**Perichondritis of the Larynx Following Typhoid Fever, with Report of a Case.**—Dr. EMIL MAYER of New York read this paper (see p. 130.)

Dr. DELAVAN of New York said that the condition was a rare one, and in about 94 per cent. of the cases was fatal. He felt that the general consensus of opinion was that dilatation was usually not successful, and that the use of the O'Dwyer tubes was the only rational treatment. He called attention to the importance of thorough cleansing of the upper air passages in typhoid fever; and said that while this measure might not prevent the occurrence of the laryngeal complications, it was the proper thing to do in order to try to attain that result.

Dr. SIMPSON of New York advised the introduction of the tubes, under ether, as in that case we could use a larger tube, and could probably use the O'Dwyer tube and not have to use a Schrotter tube.

Dr. SWAIN of New Haven referred to a case, which occurred before the present use of intubation, in which there was a double adductor paralysis. The patient died, and at the necropsy the whole of the cricoid cartilage was found necrosed.

**(a) Early Appearance of Paralysis of the Vocal Cords in a Case of Mediastinal Tumor. (b) A Case of Sarcoma of the Nasopharynx.**—Dr. WILLIAM K. SIMPSON of New York gave histories in detail of two cases as above.

In the first case, after following the course of the case for several months, noting particularly the progress of the paralysis of the cords, the aphonia and the cough, ending in the death of the patient, the author gave the findings at the necropsy; these being a large cancerous mass involving the mediastinal glands and completely filling the posterior mediastinum; carcinoma of the left lung; carcinoma of retroperitoneal glands, and an area of acute lobar pneumonia in left lung. He presented the case to put on record an instance of complete bilateral paralysis of the vocal cords, which is the rarest form of laryngeal paralysis; to emphasize the early appearances of laryngeal paralysis as an indication of intrathoracic pressure, which is often observed in unilateral paralysis, and often antedates any positive physical signs in the chest; and to note the difficulty in exactly defining the lesion in such cases, even when autopsy has shown it to be extensive.

(*b*) In the case of sarcoma of the nasopharynx the patient was twenty-seven years of age; there was a large mass nearly filling the nasopharynx, bleeding easily and looking like an ordinary adenoid growth; it gave no symptoms excepting moderate obstruction to nasal breathing and some ear symptoms in one ear, which later cleared up under local treatment, the patient for a time refusing to have the growth in the nasopharynx removed. Later he suffered from frequent and copious nasal hemorrhages and consented to operation. The growth was removed in January, 1903, by curette, under cocaine and adrenalin, with very little hemorrhage at time of operation. There had been no recurrence to date, and the patient's general health was much improved.

Dr. THEISEN of Albany spoke of a patient, with adductor paralysis and dyspnœa, upon whom he did a tracheotomy for relief of the dyspnœa. A radiograph was taken, and from that and from the other symptoms, a diagnosis was made of aneurysm. On autopsy a large mass of glands was found behind and pressing on the trachea, and both the recurrent laryngeal and pneumogastric nerves were involved in it.

**Notes on Cases of Nasal Sarcoma, with Exhibition of Pathological Specimens and Micrographs.**—Dr. J. PRICE-BROWN of Toronto read this paper. He detailed several cases of from one and a half to eight years' standing without recurrence. He advised removal of these growths by snare, when they were pedunculated; and by snare electric or cold, and forceps and scissors, when sessile, taking it out piecemeal and at many sittings if necessary, rather than doing an open external operation, which caused such deformity. He found the hemorrhage severe in all the cases, but fairly well controlled by adrenalin; and had had no secondary hemorrhage. Urged *early* diagnosis and operation, because then could operate easily intranasally, and also, of course, have less chance of recurrence.

**Additional Notes upon the Treatment of Nasopharyngeal Fibroma.**—Dr. D. BRYSON DELAVAN of New York read this paper. He called attention to the high rate of mortality which has attended the formidable methods of the older surgeons for the removal of these growths, and presented an extensive series of cases to prove the superiority of operation through the natural passages. His statistics showed that the mortality rate of such preliminary operations as resections of the superior maxilla, and of the nose, and the like, was very high, while removal through the natural passages, by such methods as evulsion, or cold snare, or electrolysis, galvanocautery snare, or electrolysis followed by snare, gave brilliant results. A brief summary of 135 cases was as follows:

| Fibroma. | Total Cases. | Cured. | Died. | Recurred. |
|---|---|---|---|---|
| Preliminary operation | 27 | 10<br>59.25 per ct. | 7<br>25.9 per ct. | 4<br>15.4 per ct. |
| Evulsion or snare through nat'l passages | 41 | 39<br>95 per ct. | 2<br>5 per ct. | 0<br>0 |
| Electrical methods through nat'l passages | 66 | 66<br>100 per ct. | 0<br> | 0<br> |

He noted the excellent work done in this field by the late Dr. Rufus P. Lincoln, and by Dr. E. Fletcher Ingals of Chicago. He also spoke of the unreliability of the published records of the various hospitals in regard to these cases, the Royal Infirmary of Edinburgh being the only institution in the world whose histories had been of any value in compiling his work. He expressed satisfaction that such a master of modern surgery as McBurney had spoken with open approval of the newer methods, and predicted that removal by preliminary operation would soon become obsolete.

**A Method of Rapid Extirpation of Nasopharyngeal Fibromata, with Report of Cases.**—Dr. GORDON KING of New Orleans read this paper. He had found that these growths continued to increase up to twenty-five or thirty years of age, and then generally atrophied. He had noted that ignipuncture, *x*-rays, and other methods of trying to make the tumor shrink up, were unavailing, and felt that radical and complete extirpation was the only satisfactory plan.

The author spoke of three special difficulties in operating: (1) That of getting at the tumor; (2) hemorrhage during operation; (3) suffocative pneumonia. He made his examinations digitally. If the growth was pedunculated, the operation was a simple one—merely snare it off. If sessile, he then operates with finger in the nasopharynx, as a guide, and passed long, strong scissors through the nose, cutting out the mass with them. The hemorrhage, though troublesome, and sometimes dangerous, during the operation, was readily controlled by pressure, and when once stopped did not tend to recur. He advised preliminary tracheotomy. Several cases were reported illustrating the method.

**The Removal of Cicatricial Contraction, or Obstruction of the Nose, by the Subcutaneous Plastic Method.**—Dr. JOHN O. ROE of Rochester read this paper, and demonstrated several of the delicate operations by means of plates, and showed a number of special instruments. He said that such contractions of the anterior nasal opening were common, resulting from ulcerations, of an acute inflammatory nature, from syphilis, from lupus, smallpox, etc. Internally, they were usually due to acute inflammations or ulcers, or frequently secondary to intranasal operations. In connection with the last mentioned cause, he urged great care, when operating, not to wound two opposite surfaces, and advised never to operate on both walls of one side of the nose at the same time. He spoke of the usual methods of treatment, by stretching or plugging for obstructions of the anterior orifice, and by nerve division and separation for internal adhesions, and said he had found them generally unsatisfactory. For obstructions of anterior opening of nose, the author used a crescentic incision, denuding the surface of the contracted or filled in portion, leaving the skin attached at one end as a long flap; then after excising the mass in the angle of the nostril, used the flap to cover in the raw surface thus exposed, or as much of it as the flap could cover, leaving the balance to granulate.

**(a) Facial Neuralgia Due to Disease in Nose and Antrum. (b) Immediate Tracheotomy for Foreign Body, with Comments.**—Dr. W. PEYRE PORCHER of Charleston read this paper. He called attention to the fact that, in very few instances, had any connection been observed, claimed, or proved between facial neuralgia and conditions in the nose. He claimed that it is really the rule rather than the exception, in these cases, that the neuralgia is a reflex neurosis due to pressure or inflammation in the nose or antrum; and deprecated the many extensive operations on the nerve trunks, and also on the teeth, when generally relief of the difficulty in the nose or antrum would cure the neuralgia. Dr. Porcher then detailed several cases with the usual train of symptoms, in which operations in the nose, relieving pressure and obstruction, stopped the neuralgia. He also reported an interesting case of foreign body in the larynx with immediate tracheotomy, and recovery. The foreign body was a small green pine burr in the larynx of a child eight months old. After unavailing efforts to extract it from above, the burr fell through into the trachea, from which it was extracted by tracheotomy. The child wore the tube for three weeks, and then made a perfect recovery.

Dr. ROE of Rochester spoke of a case of neuralgia with the pain all referred to the cheek; a large spur on the septum was found and removed, with prompt cure of the neuralgia. He reported another case in which there had been a blow on the side of the face, and drainage to antrum wall. After healing of the wound a marked facial neuralgia persisted. Upon exploration a spicule of bone was found projecting into the antrum, which was removed; and then the neuralgia ceased.

The following papers were read by title:

"Bony Cyst of the Antrum; Report of a Case," by Dr. Cornelius G. Coakley of New York.

"Removal of Nasopharyngeal Tumor; Report of Case, and Description of a New Instrument for the Operation," by Dr. E. Fletcher Ingals of Chicago.

"A Case of Gangrene of the Tonsil," by Dr. Charles W. Richardson of Washington.

"Nasal Polypi; a Study of 145 Cases," by Dr. J. Payson Clark of Boston.

"Congenital Laryngeal Stridor," by Dr. James E. Newcomb of New York (see page 127.)

"A Study of Certain Acute Inflammations at the Base of the Tongue," by Dr. Alexander W. MacCoy of Philadelphia.

"Medical Treatment of Adenoids," by Dr. William C. Glasgow of St. Louis.

**New Members.**—At the executive session of the association the following new members were elected: To corresponding fellowship, A. Anodi, Budapest; P. McBride, Edinburgh; Herbert Tilley, London. To active fellowship: Thomas J. Harris, New York; Clement F. Theisen, Albany; Francis R. Packard, Philadelphia; W. Scott Renner, Buffalo; William Lincoln, Cleveland.

**Officers.**—The following officers were elected for the ensuing year: *President*, J. H. Hartman, Philadelphia; *Vice-President*, J. H. Lowman, Cleveland; *Second Vice-President*, W. P. Porcher, Charleston, S. C.; *Secretary and Treasurer*, James E. Newcomb, New York; *Librarian*, J. H. Bryan, Washington; *Member of Council*, Jonathan Wright, Brooklyn.

The next meeting will be held at Atlantic City.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held May 21, 1903.*

CHARLES L. DANA, M.D., VICE-PRESIDENT, IN THE CHAIR.

**Symposium on Puerperal Infection.**—This was the subject for the evening, the meeting being in charge of the Section on Obstetrics and Gynecology.

**Historical Review.**—Dr. BROOKS H. WELLS presented this opening paper. He said that the fatal fever which so often took the life of the young mother in ages past, had been attributed to various causes, such as the sinister influence of an offended deity or a mysterious atmospheric influence. The first dawn of truth occurred on February 13, 1843, when there was read before the Boston Society for Medical Improvement, and in April of the same year, appeared in the *New England Quarterly Journal of Medicine and Surgery*, an essay by Oliver Wendell Holmes, who had been recently appointed professor of anatomy and physiology in Harvard College. It was bitterly assailed by the so-called authorities of the time. His initial proposition was that the disease known as puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses. He defended this with a mass of evidence just as unimpeachable now as when he placed it before his alarmed and hostile audience on that February evening. In 1847 Ignatz Semmelweiss, a young assistant physician in the large Vienna clinic, became imbued with the idea of the identity of puerperal infection and the surgical affection then termed pyæmia. He felt that many of the cases were due to infection carried by the students from the autopsy rooms to the maternity wards. This idea marked an enormous stride in advance, for it was a matter of history that after the attempt had been made to destroy the decomposing organic matters on the hands of the attendants the mortality fell lower than ever before in the history of the institution. However, this new doctrine was received with derision and

apathy just as in the case of Holmes's epoch-making and brilliant essay. Now, we knew that puerperal fever was always puerperal infection, and that with rare exceptions this infection was by the hands or instruments of midwife, nurse, physician, or the patient herself. We could not shift our responsibility by the excuse, autoinfection, since there was practically an absence of pathogenic organisms in the secretions of the birth canal. The speaker said that the object of this introduction was to bring forward a picture which would enable all to realize the great advance that had been made in obstetrics, and also to afford an opportunity for each practitioner to ask himself the question whether the marvelous reduction of the mortality from puerperal infection secured in well appointed lying-in institutions had been paralleled in private practice. To our shame it must be said, No, emphatically, no. The vital statistics of this city showed that of the reported deaths one per cent. of the entire number was from puerperal causes—in other words, one woman in twenty-five of those in the child-bearing period died from some puerperal cause, and by far the greatest cause was infection.

**Pathology and Prophylaxis.**—Dr. J. CLIFTON EDGAR read this paper. He said that endometritis was the most common lesion in cases of puerperal infection, but it was possible for the endometritis to start from a vaginitis. The two principal varieties of endometritis were septic and putrid, though there was a third variety called mixed infection about which there was yet much to be learned. It was worthy of note that in some fatal cases of puerperal infection there were no macroscopical evidences of such infection. Two illustrative cases were reported, in one of which, although no local treatment whatever had been adopted and death had not occurred until the thirteenth day after a full-term delivery, the endometrium appeared normal.

With regard to prophylaxis the speaker said that it was most important to treat during pregnancy all constitutional conditions tending to impair the general health. The antepartum tub bath must be condemned because it favored infection, not only of the birth canal but of the nipples. The necessity for great personal cleanliness on the part of the physician and nurse was insisted upon, and the value of wearing sterile rubber gloves was pointed out. The limitation of internal examinations was of special importance if the physician had recently been in attendance upon contagious or suppurative cases. With proper asepsis the danger of infection from such examinations was minimized, but it still existed, and the physician should endeavor to acquire such familiarity with abdominal palpation and the clinical history of labor that there would be no necessity for frequent examinations. In normal cases one careful examination early in the first stage, and another after the rupture of the membranes, should be sufficient for an experienced obstetrician. In many cases it was easy to conduct a normal labor without any internal examination. While one could not speak enthusiastically concerning the effect of antistreptococcus serum, it could not be denied that there was a possibility that the future would give us an effective antidote against puerperal infection.

**Intravascular Antisepsis.**—Dr. CHARLES C. BARROWS presented a clinical paper on this subject. He said that the treatment of puerperal infection should be based upon the same general principles as underlie general wound infection. It was self-evident that the source of the infection should if possible be cut off, and that free drainage should be promptly established and maintained. It has been estimated that from 6 to 10 per cent. of all deaths in women of the child-bearing age were due to puerperal infection, and hence, the medical profession was on the alert for any remedy which held out hope of improving these statistics. Dr. J. Whitridge Williams in 1899, in a report to the American Gynecological Society on the treatment of puerperal infection with antistreptococcus serum, stated that out of 101 cases of undoubted streptococcic infection, thirty-three died. The streptococcus pyogenes was the organism most commonly present in the fatal forms.

In the treatment of cases of general infection he believed intravascular antisepsis was likely to yield better results than had been obtained in the past. The idea of such medication was by no means new. Many years ago, while serving on the western plains as a medical officer in the army, he had had experience with intravenous injection of a solution of permanganate of potash in cases of bite from the rattlesnake, and this experience was responsible for the idea that intravascular antisepsis might prove successful in these desperate cases of puerperal infection. On January 13, 1903, he had reported to the New York Obstetrical Society a case of puerperal infection that had been successfully treated by injections of a 1 to 5,000 solution of formaldehyde. This communication, and the experiments by Drs. W. H. Park and W. A. Payne, reported to the New York Pathological Society on February 11, had attracted wide attention. The last two authors concluded that injections of weak solutions of formaldehyde were not only useless but positively dangerous. As to the danger of employing solutions of formaldehyde, such as the speaker had himself suggested, he said he would refer to the brilliant work of Maguire of London, who had been employing much stronger solutions of formaldehyde for years in the treatment of tuberculosis without any untoward results. Dr. Barrows said that in his own experience no injury had been done to the blood, and the convalescence had been unusually rapid and satisfactory. Certain alarming symptoms had been reported, but as such symptoms were not uncommonly observed in connection with the intravenous injection of normal salt-solution it did not follow that these symptoms were attributable to the use of the formalin. His own method was to make use of a solution of formalin in normal salt-solution, injecting it into a superficial vein while at a temperature of 100° F. The ordinary technique of the intravenous injection of saline solution should be observed. He had a series of fourteen cases treated by this method. The histories of four of them were detailed, of which the following is a fair specimen: The case was proved by bacteriological examination to be a streptococcic infection. On coming under observation, about ten days after confinement, the pulse was 150, respirations 39 and the temperature 105° F., and the abdomen was greatly distended. An intravenous infusion of 650 c.c. of a 1 to 5,000 solution of formalin was given. This was followed by a chill and a rise of temperature. but the temperature quickly fell again, and in twelve hours the temperature was 100° F., the pulse 90 and the respirations 24, and the whole aspect of the case had changed for the better. Twenty-four hours after the infusion the temperature reached the normal. Convalescence was exceedingly rapid and satisfactory, and several examinations showed no abnormality of the blood. All of the cases represented a profound type of puerperal sepsis, and they had been previously treated unsuccessfully by the approved methods. He believed a careful study of these cases would show that all of the patients appeared to be rapidly approaching dissolution at the time of instituting this treatment. The rapid improvement in their condition following the infusions, and the negative findings of microscopical examinations of the blood should at least set at rest the question as to the possible harm from such injections. He had hoped to be able to secure a series of control cases in which only salt-solution was used, but his professional work had been suddenly arrested by an accident to himself, so that this portion of the study was at present incomplete. Sajous had suggested that the good results obtained from the formalin injections were to be explained by the stimulating action of the formalin on

the adrenal system. In conclusion, Dr. Barrows said he did not wish to stand as the champion of the single chemical agent which had given such satisfaction in his own hands, but he hoped these suggestions would stimulate others to work along these lines and in a field until now practically wholly unexplored.

**Iodine Treatment.**—Dr. WILLIAM R. PRYOR discussed this topic. He said that it must be recognized that, with very rare exceptions, puerperal sepsis was a type of lymphangitis. The mortality was due to the propagation of the septic germs in points remote from the uterus. The local lesions were insignificant in comparison with those produced in remote organs. Great as was the mortality from this affection, the morbidity was sufficient to call for the most earnest attention of the profession. Impressed with the futility of performing a radical vaginal or abdominal operation for this condition, he had, in 1895, begun curetting the uterus, opening the cul-de-sac and packing both with iodoform gauze. He was soon struck with the fact that even in the worst cases there was nothing to drain away except serum, and yet the results of the treatment were perfect. He then began the examination of the uterine discharges, most of the bacteriological examinations being made by Dr. F. M. Jeffries. The cases operated on numbered thirty-seven, and only one of these gave no streptococci in the uterus, and yet even in this case they were found free in the pelvis. In all the other cases streptococci were found in both situations. In all of the cases but one he had been unable to find any streptococci at the second dressing and none after that time. This sterilization had been effected by the use of massive iodoform dressings. When iodoform was brought in contact with a serous membrane it at once gave up its iodine, and it was this which sterilized the pelvis. A sudden fall in the temperature and pulse rate uniformily followed the operation already alluded to, and in order to ascertain whether the treatment actually exerted a constitutional effect the urine was examined and it was found that a strong iodine reaction was present in the urine in five hours, and often considerably earlier. This threw light upon the possible effect of the treatment on the destructive processes taking place at remote points. Not only was the mortality under this treatment much less than with any other, but the morbidity was also decidedly less.

**Surgical Treatment.**—Dr. HERMAN J. BOLDT discussed this phase of the subject. Abscesses should be opened freely, he said, as soon as their presence was recognized, and the cavity packed with sterile gauze or gauze impregnated with some non-toxic medicament. The indiscriminate curetting, which was unfortunately being done even now to a large extent in puerperal women having a slight elevation of temperature or a chill, could not be too severely condemned. He had seen a number of deaths which could be reasonably attributed more or less directly to that procedure. The chills occurring after curettage could usually be ascribed to it. Extirpation of the uterus should only be considered in those grave instances in which the infection seemed to be limited to the uterus, and no other treatment was likely to be of avail; in other words, in the gravest forms of puerperal infection. In the reported cases of cure from hysterectomy he had been struck with the fact that they did not bear a critical analysis. We could not say from an examination of the secretions or of the blood that the patient was positively suffering from a definite and limited form of sepsis. Even if the uterus alone seemed to be the source of infection this would not invariably indicate that this organ must be removed to save the patient's life. This he would insist upon because he had known patients presenting such a condition saved without such a grave and radical operative procedure. His experience was that chills were absent in about one-third of the cases of puerperal sepsis; hence, although the symptom was one of importance it was not absolutely reliable as an indication of puerperal infection, even though followed by elevation of temperature and a rapid pulse. It was upon the continuance of such symptoms that the diagnosis of puerperal infection was based. It was very difficult to find a correct indication for surgical intervention, especially for an operation like hysterectomy. The shock from the abdominal operation was much greater than from the operation done by the vaginal route. In his experience it had been impossible to secure definite information from a bacteriological examination in less than twenty-four to forty-eight hours, but this involved the loss of too much precious time. There were instances of puerperal infection in which hysterectomy was indicated, as, for example, when there were decomposing substances in the uterus which could not be removed by the natural channels. Such cases were extremely rare, and he had not personally met with a single instance of this kind. The operation was indicated in cases of septic phlebitis, also in cases of sloughing fibromata. Women who had had criminal abortion performed upon them were most apt to suffer from the acute form of infection.

**The Danger of the Curette.**—Dr. EGBERT H. GRANDIN opened the general discussion. He said that those who had been fortunate enough to witness the phases of treatment that had arisen within the last quarter of a century would agree with him that the line of progress had been in the direction of prophylaxis. He did not think that we had acquired much more definite information with regard to the treatment of these conditions than those who practised twenty-five years ago had; on the contrary, he was thoroughly satisfied that since that time many of us, himself included, had done much harm by the surgical treatment. He had seen the time when the mortality from puerperal sepsis varied from 15 to 30 per cent., and when in hospital practice it was reduced to 0.25 per cent. This result was not obtained through the use of the knife, however, but by prophylactic measures. It occurred to him that we were not careful enough to differentiate the types of puerperal infection before beginning treatment. Sapræmia, the type of puerperal infection due to the presence within the uterus of a decomposing body, should rarely be fatal if not needlessly interfered with. In 1886, in this very room, he had read a paper before the Medical Society of the County of New York on the use of the curette. The report of the paper was widely circulated, and he now believed that this had resulted in much harm and many deaths. His present belief was that the curette should not be used in cases in which he had recommended this operation at that time, *i.e.* in that form of puerperal infection resulting from the presence in the uterus of decomposing secundines. This change of opinion had been brought about by the fact that he saw many cases in which the protecting wall against general infection had been broken down by the curette. In this class of cases the uterus was usually open, and the curette was not needed because under anæsthesia the hand alone would accomplish all that the curette should do, and could be employed without the risk attendant upon the employment of the curette. This sapræmia would remain a local condition unless by needless resort to such surgery the infection were disseminated throughout the uterus. Moreover he did not believe that in these cases the irrigation of the uterus was of any service whatever. Each irrigation carried with it the risk of new infection by the introduction of outside organisms, as, for example, the streptococcus.

**Future Possibilities.**—He had been deeply impressed with the papers presented by Drs. Barrows and Pryor. The formalin injections had certainly yielded marvelous results in Dr. Barrows' hands, and Dr. Pryor's use of iodoform had likewise yielded remarkably good results. We had all seen cases of the streptococcus type, or mixed infection, recover without either method of treatment, and yet he was willing to admit that it was probably

along the line of Dr. Barrows' suggestion that we would be able to cope with the only type of puerperal infection he feared, *i.e.* streptococcus infection. Of course, as complications arose they would be met. If pus were present in the uterus, one would naturally clean the uterus; if abscesses were found in the pelvis, these would be opened. He believed no living person could tell him when hysterectomy was indicated in puerperal infection. He had been guilty of doing hysterectomy twice, but the time when this operation should be of service was too early for us to decide as to whether or not the disease was strictly local. If the infection were general the removal of the uterus was about as logical as cutting off the woman's head.

**Saline Infusions Successful.**—Dr. H. C. Coe said that the point made here, that it was impossible to give an absolute prognosis, was only too true. He would be very glad if we could find some chemical agent which would prove inimical to the streptococcus without injuring the patient, but, to his mind, the line of investigation should be rather in the direction of looking for an antitoxic treatment. He could match Dr. Barrows' cases with six cases of severe puerperal infection that had been carried to a successful issue under intravenous injections of normal salt-solution. One of these patients presented all the appearances of one who was moribund, nevertheless recovery took place under this simple treatment. He had never yet seen a case of *acute* puerperal endometritis—say ten days or two weeks after delivery—in which he could feel that the infection was confined to the uterus.

Dr. H. N. Vineberg said that, no matter how careful the attending physician might be in a given case, sepsis might arise, and this fact should be squarely met. There was a tendency at the present day for the attending physician to shut his eyes to the possibility of sepsis, to avoid taking the temperature for a few days, and to try to conceal the disease until its severity became so great that he was compelled to do something—usually, at this stage, to call in a consultant. This suggested that there should be a revision of our teaching on this point. Every puerperal patient having a temperature over 100° F. should be looked upon as one of possible puerperal infection, and should consequently receive prompt and careful attention. He did not have the same fear of the curette that had been expressed by some of the speakers this evening. It was not always easy to get into the uterus with the finger even when there was considerable placental tissue remaining in the uterus. He was glad to see that Dr. Boldt had taken such a safe and conservative position with regard to the operative treatment. He would not think of subjecting the patient to operation unless she had been under his personal observation for three or four days. It must be admitted that in a certain percentage of the cases one could determine whether or not the infection was local or general, and consequently whether it was advisable to resort to hysterectomy.

Dr. Benjamin Torrens reported six cases of puerperal sepsis in all of which the presence of streptococci had been demonstrated in the discharge from the cul-de-sac incision. Four of the cases were treated by the cul-de-sac incision, irrigations of the uterus with saline solution and packing of the pelvis with iodoform gauze. All six patients recovered, and two subsequently became pregnant and went to full term.

Dr. S. W. S. Toms of Nyack called attention to the excellent results obtained in puerperal sepsis in the old days at Bellevue Hospital by Dr. Alonzo Clark's opium treatment. The statistics presented this evening seemed to him not to differ materially from the statistics of those times.

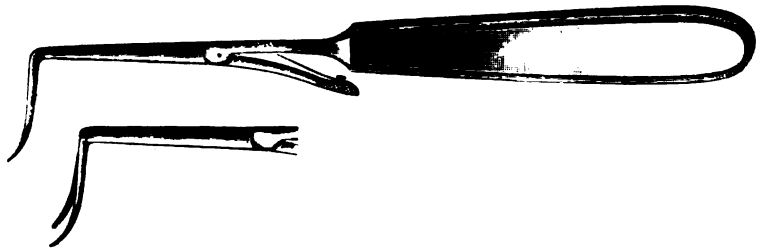
# New Instruments.

## LIGATURE AND SUTURE CARRIER.

By JOHN W. KEEFE, M.D.,

VISITING SURGEON TO RHODE ISLAND AND ST. JOSEPH'S HOSPITALS, PROVIDENCE, R. I.

This ligature carrier has the following advantages: The handle may be firmly grasped, insuring a more ready and accurate entrance into the tissues at the point desired. Either the forefinger or the thumb may be used to open the blades of the instrument to allow the placing of the ligature between the blades. The instrument can also be made with sharp points, and used to introduce sutures in the repair of the perineum immediately following labor, as well as in hernia and other operations.



The instrument is superior to ligature carriers with scissor handles on account of the perfect control of the instrument to be obtained at all times. It is made with long or short blades, the short blade instrument being suitable for the majority of cases. The long blade instrument may be used when working at a great depth, and for such cases the shank of the instrument is made longer.

The instrument may be used as both a suture and a ligature carrier. It is made by George L. Claflin & Co., of Providence.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 18, 1903:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 356 | 14 |
| Diphtheria and croup | 257 | 43 |
| Scarlet fever | 117 | 11 |
| Smallpox | .. | .. |
| Varicella | 59 | .. |
| Tuberculosis | 293 | 114 |
| Typhoid fever | 78 | 16 |
| Cerebrospinal meningitis | .. | .. |

**A Reminiscence of a Country Doctor.**—A few weeks after receiving my authority to enter into the realm of pills and powders, I stepped forth, armed with the required knowledge in the Healing Art, and filled with energy and ambition, with two goals in front of me—to startle the world with my skill, and to get rich—and pitched my tent in a small town and became that well-known, burden-bearing, long-suffering, but indispensable animal known as the Country Doctor. I had many ups and downs, triumphs and defeats, and many hardships, rarely mixed with ease and comfort.

One day, in the month of January, there was a deep snow on, the wind was blowing, it seemed from every direction, and the thermometer registered 10° below zero. I mounted "Quinine" Jim, my faithful broncho, and buttoning my mantle around me, I started on a ten-mile ride in the country, to see a patient whom I had visited the day before. Just as Jim was shaking the snow of the village from his feet, I was overhauled by a man who rode in a gallop and informed that my services were urgently needed about ten miles from the village in an opposite direction. This man, whose name was "Pink," informed me that his brother's wife was extremely ill, and he also informed me that I should be amply paid in the "coin of the realm" as soon as the services were rendered. It is needless to say that the last statement he made was the most important one; in fact, he soon had my undivided attention, because there is nothing that shortens the miles in the country physician's imagination, on a cold day, as the jingle of the guinea, at the nether end of his journey. The other patient not being dangerously sick, I concluded to give *him* a *chance*, and, turning my horse's head, I started with my friend "Pink." As is usually the case, I could not elicit anything from him as to the nature of the illness—in fact, about the only two things he seemed to realize was, that he was breathing his proportional part of the Lord's atmosphere, and that his name was "Pink." Thinking, from the meagre information I obtained, that it was a condition within the usual category of disease, I did not waste any further time, and after a two hours' ride over hills, up streams, and down hollows, I at last arrived on the scene where my patient lived—and it was also the scene where I buried many of my illusions and kid-glove dreams of the pleasures of practising medicine. I found, to my surprise and consternation, that it was a case of obstetrics ("Pink" had informed me that it was not). Imagine my condition! Oh! ye gods! without chloroform, obstetrical instruments of any kind, or even my kodak to take the baby's picture! Among my first cases of obstetrics, and a case of transverse presentation, some of ye disciples of Esculapius, who are now sitting in your office with your chair tilted to a comfortable angle, how would you like to exchange places with me on this occasion? I found three midwives (croakers of the worst type) around the bed, having exhausted their skill (?), and waiting for the patient to die. She had been in actual labor about thirty-six hours and was completely exhausted I was soon convinced that nothing but version could accomplish the desired result—and version was about the newest word in my vocabulary—perform cephalic or podalic version! I could hardly spell the names at that time, but among the faculties it has always been my good fortune to possess, is cool-headedness, and having some of the technique in mind (and the time occupied in getting consultation being the time which would decide the issue) I felt perfectly justified—in fact, felt it my imperative duty—to make the attempt. Disinfect your hands, did you say? Draw a picture, if you can, of the lowest hovel you have ever entered, not merely humble from poverty (for which I have the greatest respect), but a shiftless, filthy, unkept, and unkempt cabin. Not a chair to sit upon, only one bed, the clothing of which reeks with the dirt of years, the floors covered with the mud of months, no towels, no soap, no wash basin, no hot water, if you can draw this picture—which is true to life of the situation I describe—you will wonder how I sterilized my hands and arms. What this worthless individual (the patient's husband) had failed to provide, nature had in some measure made provision for, viz., a small brook flowed by the cabin, the water of which, had but recently filtered through the rocks and stratas of mother earth, and with some carbolized soap, which I fortunately had in my pocket, together with a clean handkerchief, I completed my process of disinfecting (?), and proceeded to relieve my patient. My old friends—the midwives—stood by in open-mouthed wonder when they saw what I intended to do, and from significant glances and whispers I could readily discern that they were pretty sure what the result would be—and after what she had already endured I was not very sanguine of a successful issue myself. And I also knew that from them the mildest verdict I could expect would be murder! After two long hours, which seemed almost as many days, I succeeded in changing the condition and made a head presentation of it. I then gave some large doses of quinine for the flagging pains, and in another two hours I had the satisfaction of delivering a real, live baby. In a few minutes I had also delivered the placenta, and then came in for the greatest ovation ever accorded me in my life, viz., from the three old midwives, whose admiration knew no bounds, and they took turn about, slapping me on the back, and declaring that I was the greatest doctor that ever lived! After another hour, during which time I expected hemorrhage or convulsions, and leaving my patient in as good condition as the surrounding circumstances would permit, I had "Quinine" Jim brought around (Jim, like myself, looked lean from lack of food), and proceeded to take my departure. The husband of the patient was well pleased with the services I had rendered and realized that I had saved his wife's life. Waiting a few minutes for him to proffer me the wherewithal, I at last introduced the subject myself and informed him that his brother "Pink" had informed me that I would receive my fee as soon as the services were rendered—had this been simply a case of poverty, I would not have mentioned the matter, but being one of those shiftless, worthless individuals, I did not feel like encouraging him in this way by allowing him to impose on me. I knew that it was not charity in any sense of the word, and felt, in this instance, that in the language of the Good Book, the "Laborer was worthy of his hire." Did this Son of Ham pay me? Not a "red"! He informed me that his brother "Pink" had prevaricated and that he did not have one dollar. Was I mad? I called for "Pink" in my best modulated tones, intending to inveigle him a short distance from the house, and vent my spleen on him, and gently tell him, among other things, the punishment meted out to the liar! in accordance with the teachings of "Dante's Inferno." In fact, it would have been a rather interesting event in "Pink's" career, but he outgeneraled me. He was no doubt aware that the question of his veracity was being discussed out in the yard, and he accordingly hied himself into the sheltering presence of the sick room, where there could, of course, be

no disturbance, and when I gently and affectionately pronounced his name, he merely put his red head out of the window and nodded it negatively. It was such a comical scene that I was really more amused than angered, and, of course, seeing now no prospects of any compensation for my services, I decided to encourage this serio-comedy a little further, and to that end I asked the husband if he was aware that I was a notary public, and as such, I had the authority to administer an oath. He did not know that I was. I informed him that such was the case, and I also asked him if he knew the penalty of swearing a falsehood. He did. I accordingly, with all the solemnity I could command, administered an ironclad oath to him, the purport of which was that he would pay my fee—according to promise—in monthly instalments. And it is needless to say that I have never seen him from that day to this. After he took this oath (which was "To support the Constitution of U. S." among other clauses) I mounted my steed and proceeded homeward. I do not think that ride shall ever fade from my memory. Cold, tired, hungry, sick and discouraged, and during that homeward journey I resolved that I would never practice medicine another day. Arriving home about dusk, I turned out my jaded horse, fed him and told him that we would bid adieu to our honorable calling and thus make room for some one more worthy, and, on my way from the stable to my boarding-house I bid an affectionate farewell to my faithful saddle-bags and gently tossed them over the garden fence. I informed the folks at my boarding-house of my resolution, and after numerous solicitations from my landlady to eat some supper, which I was too sick—from hunger—to do, I retired to my lonely couch to think and dream of the hopelessness of suffering humanity now that I had retired forever from the practice of medicine. So might my career have ended as a physician, but for the restorative effects of ten hours in the arms of Morpheus, and the fact that my landlady having espied my saddle-bags in the garden, stealthily placed them so that when I awoke my eyes rested, first, upon them, as though I had placed them there as usual. These two facts, perhaps, prevented me from carrying out my resolution. For it is a part of this reminiscence to say that I arose from my couch, shook off the discouragement of the previous evening, forgot my resolution, saddled "Quinine" Jim, and started on my usual rounds.

B. Cliff Wilson, M.D.

Powellsville, Ohio.

**Quarantine Regulations of the United States for Leprosy.**—Vessels arriving at quarantine with leprosy on board shall not be granted pratique until the leper with his or her baggage has been removed from the vessel to the quarantine station. No alien leper shall be landed. If a leper is an alien passenger and the vessel is from a foreign port, action will be taken as provided by the immigration laws and regulations of the United States. And to this end the case shall be certified as a leper and reported to the nearest commissioner of immigration. If a leper is an alien and a member of the crew and the vessel is from a foreign port, said leper shall be detained at the quarantine at the vessel's expense until taken aboard by the same vessel when outward bound. Such cases of leprosy should be promptly reported to the Collector of Customs at the port of arrival of the vessel, and the Collector shall exact a bond from the vessel for the reshipment of the said alien leper upon the departure of the vessel.

**The Hay-fever Pollen.**—Professor Dunbar of Hamburg, claims to have discovered in the pollen of flowers the poison which causes hay fever, and also its antidote.

**A Physician's Will.**—In his last will Dr. Ladislaus Jasinski, a leading physician of Lemberg, Galicia, bequeathed $65,000 to a fund for assisting widows of doctors, and ordained at the same time that not more than eight shillings ($2) should be spent on his funeral. His numerous orders and medals of distinction he had given away the day before his death to a hostler and a postman.—*New York Tribune.*

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended July 18, 1903:

## CHRONIC POSTDIPHTHERITIC LARYNGEAL STENOSIS AS A CAUSE OF PERSISTENT INTUBATION OF THE LARYNX.*

BY HENRY W. E. BERG, M.D.,
NEW YORK.

VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS—ADJUNCT PHYSICIAN TO MOUNT SINAI HOSPITAL.

WHEN intubation of the larynx was proposed and initiated by Dr. O'Dwyer for acute stenosis of the larynx in diphtheria, the object in view was to render the larynx an open tube for the short period during which a stenosis produced by the diphtheritic or other inflammatory process closed or narrowed the lumen of the laryngeal canal. This period rarely exceeded seven days. It was found by experience that after this comparatively limited period of time, the removal of the tube was followed, for a few hours, by some difficulty in breathing, which rapidly subsided and was evidently due to spasm of the glottis, or slight temporary disability of the vocal cords. Both of these conditions soon disappeared, and the fortunate little patient had been saved from the frightful death by asphyxiation.

With the introduction of the antitoxin treatment, this average period of seven days for wearing of the tube was reduced to about four days, the conditions which had caused the stenosis being favorably and more rapidly influenced by the antitoxin treatment.

Cases, however, occurred in which the removal of the tube was followed in a few minutes, or hours, or days by a return of the stenosis, so severe that reintubation was necessary. In these cases the removal of the tube after two days or thereabouts was followed by a cure of the stenosis. Exceptional cases again required reintubation, to be followed in a few days by extubation and cure. Still an occasional case required reintubation frequently, until finally the physician was forced to the conception that the stenosis was no longer due to the causes which necessitated the first insertion of the tube, and which were dependent upon and the pathological result of the diphtheritic process, but that more or less permanent pathological changes had occurred in the glottis, larynx and trachea which had narrowed the lumen of the respiratory canal, producing a chronic stenosis requiring prolonged or persistent intubation. Some cases, too, occurred which a day or two or more after the primary intubation would cough up the tube. In many of these such autoextubation followed upon the disappearance of the false membrane, and diminution of the swelling and œdema of the laryngeal mucous membrane and glottis, and left the patient able to breathe without the tube. In a few cases, however, such autoextubation, instead of leaving the patient *freed* from urgent dyspnœa, was followed almost immediately by such foudroyant symptoms of stenosis that the tube had to be rapidly reinserted. In many of these cases the autoextubation occurred so frequently, and was so rapidly followed by urgent dyspnœa that a larger tube than the age called for was inserted, or the configuration of the tube was changed, rendering the autoextubation more difficult. Such cases thus become cases requiring persistent intubation of the larynx; although in these cases, as contradistinguished from those referred to above, the condition was not a chronic laryngeal stenosis but, as I shall show, a chronic laryngeal paralysis, the condition being due to paralysis of the vocal cords. For purposes of systematic consideration I should, therefore, divide cases of persistent intubation of the larynx, or, as O'Dwyer called them, "cases of retained intubation tube" (*Archives of Pediatrics*, 1897), into the following groups:

1. Cases of prolonged stenosis in which the original conditions which necessitated the intubation persist beyond the usual length of time.

2. Cases of prolonged stenosis, due to pathological changes which have arisen during or subsequent to the primary intubation, and are not those of the diphtheritic process which necessitated the primary intubation. Such lesions are due (*a*) to the injurious effect of the intubation tube upon the structures of the glottis, larynx, or trachea; (*b*) to traumatism produced by the operator either during intubation or extubation.

3. Cases of persistent intubation due to paralysis of the vocal cords: (*a*) temporary paralysis or spasm; (*b*) persistent paralysis.

Before considering these different groups of cases, a word as to the frequency of persistent tube cases. I would exclude cases belonging to the first group, in which the reintubations are necessitated by causes temporary in character although more protracted than is usual, and which I prefer to call prolonged or protracted tube cases, in contradistinction to those of the second and third groups, which are properly described as persistent tube cases. Fourteen cases belonging to these two classes occurred in the Willard Parker Hospital, in the diphtheria service, and were treated from December 1, 1900, to April 1, 1903, which Dr. E. G. Bryant, resident physician of the Willard Parker Hospital, who is much interested in these cases, has been kind enough to tabulate, for me (see table on page 162).

I find that we have treated in the hospital, by means of intubation, during 1901, 214 cases with 66 recoveries; 1902, 258 cases with 114 recoveries; 1903, to April 1, 106 cases with 41 recoveries. Total number of intubation cases from January 1, 1901, to April 1, 1903, 578. Total number of recoveries, 221. Total number of persistent tube cases, 17 (13 in Dr. Bryant's table, 1 occurring since and 3 sent out of the hospital by request to be treated outside).

The percentage of recovery is thirty-eight. To those who know the conditions under which intubation cases are sent into the hospital, this will seem a large proportion of recoveries. Many of these cases are intubated outside of the hospital, under adverse conditions, and sent to the hospital when a fatal result, generally from bronchopneumonia, is expected. Frequently, too, cases are not sent in until after the first extubation, when, reintubation becoming necessary, the outlook of prolonged treatment discourages the relatives, and they consent to the removal from the home of a little sufferer whom they were anxious to keep under their own supervision as long as circumstances permitted. It is

*Read before Section on Pediatrics, New York Academy of Medicine, May 14, 1903.

evident that from such material the chronic tube cases are more apt to develop. It has been an interesting point in my inquiry to find that out of the seventeen chronic tube cases reported some were intubated, and some extubated once outside of the hospital by physicians not connected with the Willard Parker Hospital.

The duration of time that the tube was worn in these cases was from two and one-half months in the shortest to eighteen months in the longest. From the length of time these cases wore their tubes they are entitled to be called chronic tube cases. When O'Dwyer reported his first two cases of "retained tube," the condition was looked upon as exceedingly rare. One or two cases a year was all that even so large a service as ours could show in earlier years, notwithstanding the fact that cases came to us intubated outside of the hospital in as large a proportion as at present. This increase in these chronic cases has been noted by other authorities, especially Bokai, *Deutsche medicinische Wochenschrift*, 1895, No. 46; Gesellschaft für Kinderheilkunde, Hamburg, 1901, and "Das Intubationstrauma", *Deutsche Zeitschrift für Chirurgie*, 58, Bd., 1901. He ascribes these chiefly to decubitus, from pressure of the tube, and shows that while under the serum treatment the average duration of wearing of the tube for the relief of stenosis has been diminished from

five days to a little less than three days, and the percentage of recoveries has almost doubled, the cases that die show in a larger proportion severe decubitus. He ascribes this to the fact that only the very severe cases die under the antitoxin treatment, and these are subject especially to severe pressure here. Dr. Gallati considers these chronic tube cases of such importance and increasing frequency that he has written an admirable monograph on the "Decubitus from Intubation Tubes" (Intubationsgeschwur, Wien, 1902). Papers on this subject are being contributed all over the world by authorities connected with large diphtheria services, and these chronic tube cases appear to be especially frequent abroad. There is no question that their frequency has increased, even in this country, yes, even in this city, since O'Dwyer's death. How much has the removal of the conservative influence of O'Dwyer upon physicians and instrument makers who would modify and improve the O'Dwyer tube had to do with the increase in chronic tube cases?

It will be recalled that our classification of persistent tube cases included in the first group cases of prolonged stenosis in which the pathogenetic factors of the stenosis are the same as those which produce the stenosis primarily in any case of membranous croup, such factors in these cases having persisted longer than usual. The chief pathological factors which produce a laryngeal stenosis which requires intubation for its relief are, inflammation and thickening of the mucous membrane of the larynx and upper trachea, the deposit of diphtheritic pseudomembrane on this site, and œdema of the subglottic tissues. Œdema of the glottis itself is seldom a factor in the causation of an intubation, for although it does occur in croup complicating pharyngeal and tonsillar diphtheria, yet its pressure to a sufficient extent to produce closure of the glottis necessitating intubation is generally an indication for tracheotomy, such dyspnœa not being sufficiently relieved by intubation. Cases, however, are frequent in which a moderate œdema of the glottis exists, but not sufficient to become a marked factor in the production of the stenosis. The swelling and thickening of the mucous membrane is the factor which yields most readily to the intubation treatment. Nevertheless, it frequently persists longer than five or six days, the duration of the primary intubation. This, as well as the length of time that the diphtheritic exudate persists, can best be studied in diphtheria of the pharynx, when the process reveals itself *ad oculos*. Since the days of serum-therapy, the swelling and the exudate diminish and disappear very much faster than in the pre-antitoxin period. Indeed, the pseudomembrane disappears so rapidly that frequently by the fourth or fifth day after the injection of antitoxin a pharynx and tonsil that showed a large amount of exudate on admission into the hospital is entirely clear. The exceptional cases are those in which the exudate is not only on the surface, but in the stroma of the mucous membrane. Here the swelling persists until practically the superficial layers of the mucous membrane have exfoliated, or, in exceptional cases, until gangrenous patches of mucous membrane have separated, leaving ulcers which gradually heal. In the larynx, however, the presence of the tube causes a sufficient pressure to aid in the reduction of the swelling, and indeed to aid in the exfoliation of pseudomembrane, and retard the production of new exudate. It is owing to influence of the serum treatment in the exfoliation of the pseudomembrane and the reduction of the swelling of the mucous membrane that the average length of time during which the tube is needed in diphtheritic stenosis has been reduced from five to six days to about three days. I have seen, however, pseudomembrane persist in the throat as long as twenty days without antitoxin, and even under serum treatment have seen membrane persist in the pharynx for twelve days, in private practice, in an exceptional case. I do not know the maximum duration of pseudomembrane in our

hospital cases, under the serum treatment, although in the pre-antitoxin days this question was studied in relation to the efficacy of various kinds of local irrigation. I have said sufficient, however, to show that when the tube is removed on the fifth or sixth day, even under serum treatment, it is often feasible for the persistence of pseudomembrane and mucous swelling to necessitate a reintubation. Such reintubation may not become necessary until an hour has elapsed. In most cases the necessity of a single reintubation is due to this cause, and in rare cases even a third reintubation after two or three days may be due to this cause. I do not think, even in the absence of symptoms of any laryngeal complication, such as I shall recount later, that a reintubation after the eleventh day should be looked upon as necessary, by swelling and pseudomembrane.

Subglottic œdema of the mucous membrane of the larynx immediately underneath the vocal cords is an important factor in the production of laryngeal stenosis, and especially in a persistent stenosis beyond the sixth day. While such subglottic œdema is not the causative factor in the production of the stenosis of such cases as I report in this paper, and to which only I would apply the term of chronic tube cases, yet it is a factor in the causation of prolonged tubage of the larynx in cases which are intubated and reintubated up to the twentieth day. Immediately underneath the vocal cords the mucous membrane is more loosely applied than it is to the rest of the larynx, and the tube itself, owing to its construction and to its position in the larynx, helps to drive the œdematous swelling into the immediate subglottic tissues. The neck of the tube is grasped by the vocal cords above, while the retentive swell of the tube rests immediately above the cricoid, so that the portion of mucous membrane upon which there is least pressure is the subglottic space, if I may so call it. While these three factors, if persisting for too long a time, may necessitate temporary reintubation, it is important to remember that all of them are comparatively short in duration, and while they may cause prolonged tube cases, they are not a factor in the causation of what I have termed "postdiphtheritic laryngeal stenosis," necessitating persistent intubation of the larynx with extubation at intervals, followed by almost immediate reintubation. This class of cases I have placed in the second and third groups. They are characterized by long duration, many months and sometimes several years, depending upon the type of lesion which caused the stenosis. Such lesion may be due to an injurious effect of the tube acting upon the structure of the glottis, larynx or trachea, or it may be produced in the course of the operation of intubation or extubation. To understand how a lesion can be the result of the injurious action of the tube, it will be proper to recall to your attention a few salient points concerning the structure of the O'Dwyer tube and its position in the larynx.

When O'Dwyer first thought of tubing the larynx for the relief of the dyspnœa of membranous laryngitis he had already tried a soft catheter passed through the larynx, and a wire arrangement shaped somewhat like a bivalve speculum. Both of these expedients were discarded as failures. He finally thought of passing a small metal cylindrical tube through the glottis, with a flange over the vocal cords to keep it from dropping into the trachea, to which a string, passed through an eyelet in the tube, was attached. This string was allowed to protrude from the mouth and tied to the ear of the patient. He soon found that such a tube was very readily and frequently coughed out, the patient succumbing to the rapidly supervening dyspnœa. To avoid this, O'Dwyer introduced what is known as the retention swell in the tube. From this swell the tube narrowed to the neck and to the tracheal end, in conformity with the general configuration of the larynx and trachea. The vocal cords grasped the tube at its narrowest part, above; thus the head of the tube, with a slope in conformity with the epiglottis, rested over the vocal cords (true and false). The retention swell rests immediately above the cricoid cartilage, and its diameter is such that if the tube be of the proper size for the age of the patient, it cannot be pushed through the cricoid into the trachea without fracturing the cricoid; so that the tube is prevented from falling into the trachea by the retention swell, and not by the head of the tube above the vocal cords. Indeed, in paralysis of the vocal cords, very slight force would send the head of the tube through the vocal cords if the cricoid permitted the passage of the retention swell. This retention swell furthermore prevents the coughing up of the tube, especially while there is swelling of the glottis and laryngeal mucous membrane, and while exudate is still present. The pressure of even a violent cough is insufficient to send the tube through the glottis, except where the vocal cords are weakened or paralyzed. In such cases in the Willard Parker Hospital we have sought to obviate this too early autoextubation by increasing the size of the retention swell in the tubes used for such cases. The retention swell is thus the most important part of the tube. It prevents the dropping down and the coughing up of the tube. The head of the tube has much less important functions. These are—first, to prevent the tube from slipping into the glottis and thus permitting the vocal cords to ride above the end and lumen of the tube; second, to enable the fingers of the operator readily to find the tube and its opening with the blades of the extractor.

Although the shape of the O'Dwyer tube, as constructed by him, conforms to the lumen of the laryngobracheal tract as far as the exigencies of the function of the tube will permit, nevertheless it must not be forgotten that the tube is a foreign body, rubber or metal, and that the laryngeal mucous membrane is soft and lies between the tube within and the hard cartilage without. Pressure, therefore, on the part of the tube will produce pressure sores, which the Germans term "decubitus." Indeed, pressure is not necessary, nor is it present in a properly fitting and properly constructed tube, to produce decubitus. Such lesions result more frequently from the rubbing of the tube against the mucous membrane over the prominent points of the tube. For the tube is not stationary in the larynx. It is always vibrating with the cough, giving rise to the characteristic "tube" cough, as it interferes with the vibration of the vocal cords. It moves up and down with the act of swallowing, with the cries of the patient, even with the movements of respiration. It is not remarkable, therefore, that the decubitus lesion is seen in so large a proportion of cases. On the contrary, it is an evidence of the wonderful genius of O'Dwyer in adapting this tube to the needs of the human larynx that the decubitus is a clinical factor so seldom. The mucous membrane in these cases, furthermore, is the seat of the malign activity of the diphtheria and pus organism, and is swollen and congested, all of which tends to increase the liability to pressure sores.

Decubitus sores vary in their severity, some of them showing only a slight abrasion of the superficial layers of epithelium, others showing a lesion involving the destruction of the cartilage with

abscesses of the surrounding soft structures and purulent infection of the mediastinum.

It is a curious fact that decubitus is rarely seen affecting those portions of the laryngeal mucous membrane which is covered with exudate. Some writers speak of decubitus involving even the cartilages underneath the exudate. Decubitus may occur in some cases very early, as early as twenty-four hours after intubation. As would be expected, the longer the tube is retained the greater the liability to decubitus. This decubitus is the most important causative factor, as I shall show in the production of persistent tube cases. It is most frequently located at the anterior wall of the trachea, below the cricoid, caused by the lower end of the tube moving up and down against the trachea, the lower end of the tube being thrown forward as the head of the tube is thrown backward by the closure of the epiglottis over it. Decubitus is next most frequently situated above the cricoid cartilage over the lateral and anterior wall of the larynx. This is due to the pressure and rubbing of the retention swell against the mucous membrane above the cricoid. The next site of election for decubitus is on the under surface of the epiglottis, and below the point of its junction with the thyroid cartilage; this is due to the pressure of the epiglottis and larynx against the head of the tube, and its straight anterior border. Other portions of the mucous membrane may be the seat of decubitus ulcers, depending upon the variations of the larynx in individual cases. By far the most important of all of these is the decubitus above the cricoid, laterally and in front. The pressure literally at the point where the thyroid overlaps the cricoid cartilage, a frequent site of decubitus, is of especial importance, because here is the entrance, on both sides, of the recurrent laryngeal nerve, the motor nerve of the larynx. Pressure and decubitus here produce paralysis of the motor function of this nerve. I believe that this paralysis of the vocal cords is the cause of cases of the third class of persistent intubation, which are characterized by repeated coughing up of the tube. Indeed, auto-extubation is a frequent symptom of retained tube cases due to cicatricial stricture of the larynx following decubitus.

While such decubitus may occur in tube cases with the use of the most orthodox O'Dwyer tube, I believe that the most fruitful source of the decubitus is the unskilful modification of the O'Dwyer tube by operators who, both in their writings and practice, seem to forget the principles upon which the O'Dwyer tube is constructed. Thus it is evident that he who increases the length of the tube beyond that of O'Dwyer favors the occurrence of decubitus on the anterior wall of the trachea, and adds to the liability of injuring the larynx in the process of intubation, and especially extubation. For the space between the roof of the mouth and the glottis is limited, and accommodates the tube and the extractor with safety only to expert technique. So the retention swell, made too large for the regulation intubation set, is apt to exert increased pressure. A like result will happen if the distance between the retention swell and the neck of the tube is kept well down upon the vocal cords by the epiglottis, here sometimes producing decubitus, and the retention swell is pressed upon the mucous membrane of the cricoid, and thus the most dangerous form of decubitus will be produced. The same result will occur if, as some surgeons do and advise, the largest possible tube, instead of the proper tube for the age, be selected. I have a so-called improved tube, the lower end of which was prolonged on the right in the shape of a beak, the object being to put aside the swollen tissues as the tube entered the croupy larynx. I do not know of a more dangerous modification, for this beak denudes the mucous membrane of exudate, which it pushes before it, at the same time producing a lesion of the laryngeal mucous membrane, which becomes a good site for new exudate, or decubitus, while the beak produces a jagged puncture and tear of the lateral wall of the trachea. This tube is made without the obturator, the lower end is open, and membrane separated by the projecting beak finds no obstruction to its entrance into the tube. Such a tube would be readily plugged in the process of intubation. This set also uses but one combination instrument for extraction and intubation. The blades of this are large; hence a large lumen to the tube, hence an ample neck to the tube, thus favoring paralysis of the vocal cords from overstretching. The retention swell is too small and not properly placed. The head is cupshaped, and forms a good place for the collection of food, membrane, etc. And yet children survive even such tubes, or the eminent authority would not have recommended it. Absolute smoothness of the external surface of the tube, which lies against the laryngeal mucous membrane, is requisite if we would not encourage decubitus, for even a most superficial abrasion increased by the attribution of a rough tube is the starting point of a decubitus sore. Nor is such a roughening of the external surface of the tube justified by the excuse that such tubes are not coughed up. This purpose is fully met by the smooth retentive swell of the O'Dwyer tube, and if decubitus and pressure paralysis of the vocal cords does not occur, too early autoextubation will not occur. The autoextubation due to the diminution of exudate and swelling means that the tube is no longer required or is therefore conservative.

Now why is decubitus so much to be dreaded in tube cases, and what is its connection with persistent intubation cases? These questions are best answered by recounting the pathological processes occurring in and around the larynx which originate in decubitus. These lesions, produced, as I have stated, by the action of the tube on the larynx, may begin to heal as soon as extubation is accomplished, without injurious effects, and without giving rise to any symptoms. That this occurs very often is shown by the comparatively small percentage of chronic tube cases as compared with the large percentage of cases which die from diphtheritic croup in which decubitus is found. In other cases the decubitus may give rise to swelling of the surrounding tissues and stenosis, necessitating a reintubation. Such reintubation results in an aggravation of the decubitus; so that when extubation is again done, reintubation again becomes necessary at shorter and shorter intervals, until the patient requires a reintubation almost immediately, or else asphyxia supervenes. At first, as I have said, this reintubation is caused by a stenosis due to the swelling of the tissue around the decubitus soon after the tube has been removed. It is claimed that as long as the tube is not removed for at least a few days such decubitus can not heal, and hence a cicatrix can not form, so that cicatricial structure of the larynx in such cases is impossible. But this view is certainly incorrect, for I have seen chronic tube cases in which the early intubations were done with ease and without resistance, while later on the resistance of a cicatrix is felt in intubating. This cicatricial stricture becomes gradually narrower, so that with repeated intubations smaller tubes must be used. Yet this occurs in patients who have gone without the tube at no time more than a few hours. In such cases the decubitus undoubtedly heals; the granulations

and the conservative contraction of the extruding extrinsic muscles of the larynx pressing the tube away from the decubitus until cicatrization has taken place; this cicatrix contracts and goes on to form a cicatricial structure of the larynx. As long as a tube is *in situ* in the larynx, passed through a stricture of this sort complete closure or atresia of the larynx can not occur. But when, either owing to the difficulty of intubation through the strictured larynx or through an ill-advised attempt to give rest to the larynx, by doing a tracheotomy the O'Dwyer tube is dispensed with, then the laryngeal stricture goes on to more or less complete atresia of the larynx, so that even a thin probe can not be passed through the lumen. Sometimes tracheotomy is done for cases of autoextubation, for the danger of leaving the patient dependent upon an intubation tube which may be coughed up at any instant is obvious. In such cases, if the cause of the extubation is paralysis of the vocal cords, atresia of the glottis occurs shortly after the intubation tube is removed. Finally, atresia of the larynx may also be due to opposing decubitus granulating ulcers coming in contact with each other, and becoming adherent. Decubitus may also increase in depth and extent, giving rise to destruction of cartilage of the larynx and trachea and perilaryngeal and peritracheal abscesses which discharge into the respiratory tract or œsophagus, or externally the pus may burrow downward and give rise to mediastinal abscess. The following is the history and autopsy of a case of persistent intubation of the larynx, with decubitus and destruction of the cricoid upper tracheal rings, extensive post-perilaryngeal abscesses, which finally caused death from pneumonia, after a secondary tracheotomy: J. K., age three years, admitted November 1, 1901; ill three days; local, no membrane. Marked croup and retraction and right cervical adenitis; antitoxin previous to admission. Intubated on admission. Tube removed five days later and almost immediately replaced; again on seventh day, with same result. From then on for three weeks more or less frequent autoextubation and almost immediate retubation. After this, child coughed up tube only at long intervals—no particular exciting cause, the child being up and about. General course of disease mild from time of intubation. When extraction was performed it only meant reintubation, although she would go without tube at times for some minutes. This continued till January 13, 1903, when she developed measles from exposure to a recently admitted case, and was transferred to North Brother Island. Returning to us February 10, patient continued to do well till March 24, when she developed a temperature and general malaise, which could not be accounted for. Physical examination negative. Four days later the front of the neck became red and indurated, the following day there was swelling of cervical glands and the expectoration was purulent and tinged with blood. The next day an incision in the front of the neck was made and a tracheotomy tube inserted. The child lived only two days following operation. Died March 31, 1903. Post-mortem examination revealed a post-laryngeal abscess with a sloughing of the cricoid and upper tracheal rings.

There are no symptoms by which decubitus can be positively recognized during life, until its effects—stricture, atresia, abscess, etc.—have appeared. One symptom, however, positively indicates the presence of decubitus, and that is late autoextubation, occurring after often repeated reintubations. Early autoextubation, which occurs as a result of diminution in swelling, membrane, etc., which I have discussed above, is not usually followed by a reintubation. It is conservative and does not signify the presence of decubitus. Late autoextubation, when not due to pressure paralysis of the vocal cords, is an almost positive symptom of decubitus, yet many cases of decubitus going on to the production of chronic stenosis of the larynx do not give rise to autoextubation.

In the list of chronic tube cases, which I present with this paper, the time of occurrence of autoextubation is especially noted. Where it was present as a symptom, autoextubation, due to decubitus, may be the result of the cicatricial stricture expelling the tube at intervals, or to a paralysis of the vocal cords owing to pressure and decubitus, by the retained tube, on the recurrent laryngeal nerve as it enters the larynx behind the facet on the cricoid cartilage for the thyroid cartilage.

The following is a history and autopsy of a case of repeated autoextubation in a chronic tube case resulting in pneumonia and death. I present the specimen, which shows marked decubitus and partial cicatrix anteriorly and over cricoid:

F. C., age three years, admitted August 13, 1902, three days ill. Local examination gave negative results. Marked croup and retraction. Condition serious. Antitoxin 3,000 units. Intubated shortly after admission. Developed pneumonia at night, posteriorly. First extubation seventh day after admission; reintubation was necessary twenty-five minutes later; autoextubation three days later; eleventh day, reintubation in forty-five minutes. General condition improving, Pulmonary condition much improved. Autoextubation and reintubation then daily for five days. After this there was a lapse of a week, when the tube was extracted, but had to be replaced very soon. This time child developed an enteritis with a temperature which was thought might be due to a tuberculous condition. Tube removed twenty-four days later, but had to be immediately replaced. Occasional rises of temperature during the next two months led to the suspicion of the presence of tubercle bacilli, but they could not be found in sputum. Tube coughed up at irregular intervals, several days apart, when child would go without it, sometimes only a moment, and again for from six to eight minutes.

December 24. New and more extensive area of dulness made out with increased elevation of temperature. Patient losing strength very rapidly, and continued to do so until death occurred January 2d, 142 days after admission.

Examination of larynx showed subglotteal thickening, with a small ulcer partially cicatrized anteriorly.

Now we come to consider chronic tube cases due to traumatisms produced by the operator during the process of intubation or extubation. Such traumatism produced during the operation may heal promptly, giving rise to no symptoms, or may heal under reintubation for a short period, or they may give rise to chronic stenosis of the larynx, for the relief of which prolonged intubation becomes necessary. This prolonged intubation gives rise to decubitus with all of its sequellæ, and thus a persistent tube case is developed. Even slight traumatisms of the laryngeal mucous membrane are followed by serious results, for abrasions are the ready site of a decubitus ulcer that will not heal. Such lesions may be produced by a perfectly orthodox set of instruments by an inexpert operator. Thus a false passage may be made, the epiglottis may be fractured, or other accidents recounted in every work on intubation may occur. There is one fault in the O'Dwyer apparatus which is very difficult to remedy, the knowledge of which, however, will save

the operator from many traumatisms which I must discuss here, the more so because writers on intubation have devoted no attention to it.

In extubation, when the blades of the extractor engage in the head of the tube, and the operator raises the tube from the larynx, the shoulder of the extractor strikes the roof of the mouth (hard palate) when the tube is still half its length inside of the larynx, so that, in order to bring the tube completely out of the larynx the operator depresses the handle of the extractor, throwing the lower end of the tube against the posterior wall of the larynx in the median line. If the extubation is done hurriedly, as the inexpert operator is apt to do, he will tear a groove in the mucous membrane of the posterior wall of the larynx. Or, if he turns the shoulder of the extractor to either side, he may produce a similar lesion of the opposite lateral wall of the larynx. This is especially apt to occur in children under two years of age, owing to the small space between the roof of the mouth and the glottis. That O'Dwyer was conscious of this difficulty is shown by the hinge which he placed on the obturator, which is withdrawn from the tube after intubation, the purpose of this hinge being to facilitate the removal of the obturator.

Could the tube be constructed with such a hinge joint, its removal would be equally facilitated, and although I hesitate to suggest a change in the O'Dwyer apparatus, I have devoted some thought to the construction of such a tube. It is practicable to use, for different ages, different extractors, the shoulder of the instrument being made little more than two-thirds the height of the present instrument for children under four years and the present instrument for older children. I should also warn against rapid extubation. The operator should be deliberate and slow. The extractor with tube having been raised as far as it will go, the handle should be slowly depressed in the median line and the tube carefully delivered without injury to the larynx. All of this naturally presupposes sufficient and proper technique for the handling of the patient.

The "tubes courts" of Bayeux are short, and could therefore be extracted readily with the extractor, but the inventor uses no extractor, but expresses or enucleates them by normal expression of the larynx just above the cricoid. I should fear that the general acceptance of such a practice would result in far more traumatisms of the larynx in inexpert hands than now occur with the long O'Dwyer tube by the inexpert use of the extractor.

Cases of chronic intubation produced by temporary or persistent paralysis of the vocal cords I have unavoidably discussed in the course of my remarks on cases of chronic intubation of the larynx belonging to my second group. The symptomatology of prolonged stenosis or chronic stenosis of the larynx is of importance chiefly for differentiating the various causes that produce the stenosis.

The first group of cases, in which the stenosis is caused by a persistence of the pathological conditions which cause the initial stenosis of membranous croup, are characterized by a gradual lengthening of the periods between the extubations and intubations until a period arrives when a reintubation is no longer necessary. In some of these cases the reintubations are rendered necessary by spasm of the glottis, which supervenes shortly after extubation. In most cases this can be avoided or alleviated by a small dose of morphine, gr. $\frac{1}{16}$ to a child of two years or over, hypodermatically. Rest and avoidance of excitement are adjuvants to this. In these cases, if autoextubation occurs, it is of the conservative type and signifies subsidence of membrane and swelling. The dyspnœa does not recur after these autoextubations, as it does immediately after the late autoextubations frequent in the second and third group of cases.

In the second class of cases the symptoms pointing to the presence of an increasing cicatricial stenosis are (1) the increasing difficulty of passing the propre tube into the larynx and through the stricture; (2) autoextubation late in the course of the case, due either to paralysis of the vocal cords, or to the forcing out of the tube from the larynx, owing to the contraction of the stricture around the lower end of the tube below the retention swell.

When paralysis of the vocal cords exists the condition can be recognized by the intubator, who feels the absence of all resistance to the entrance of the tube at the glottis. This resistance is normally very slight, but still one of which the intubator is conscious; while in paralysis of the vocal cords the sensation is that of putting the tube into a large cavity. Peritracheal and perilaryngeal abscess are readily recognized externally. Generally they come to the surface, are incised and drained. Sometimes they rupture into the larynx, trachea, or pharynx; sometimes they give rise to general suppurative processes in the mediastinum, or even a general pyæmia. Atresia of the larynx is recognized by absolute inability to pass even the smallest tube. In these cases tracheotomy has, of course, been done long before such atresia has occurred. Indeed, the condition can not occur as long as the larynx is pervious to a tube, and a tube is *in situ*. A sound passed through the tracheal wound upward will enable us to know whether the atresia is limited to the glottis and vocal cords, or the upper part of the larynx, or the whole of the larynx.

*Prognosis.*—In the first class of cases without decubitus, prognosis is good. These cases suffer from a prolonged period of repeated intubation, and then recover. But it must not be forgotten that the longer a tube is worn the greater the liability to decubitus with resulting organic stricture of the larynx. So that many cases which begin as cases of prolonged intubation become later on cases of chronic intubation with persistent stenosis.

In the second class of cases much depends upon long and persistent treatment in the manner I shall indicate. While the condition is curable in about 60 per cent. of the cases in our experience at the Willard Parker, the prognosis is very much more serious when such cases are treated by those not experienced in expert intubation. Thus a case not included in the series which I report in this paper was removed from the hospital to a general hospital by the parents. While the child was waiting there for the day of operation, she coughed up her tube one day, and before a tracheotomy or reintubation could be done she was dead.

Such accidents in the wards of the Willard Parker are always expected, and the facilities for prompt reintubation or tracheotomy are always at hand. I must not forget to insist that any surgical operation which may be contemplated upon such a strictured larynx should be preceded by a tracheotomy immediately after removing from a hospital, with facilities for rapid and expert intubation.

*Treatment.*—The prevention of decubitus and injuries to the larynx from an important part of the treatment of chronic tube cases. How such lesions can be prevented I have shown in discussing the manner in which they are produced. Thus, proper tubes and none but the properly constructed O'Dwyer tubes and accessories are "proper" in my estimation; care in the technique of, and deliberation

in the performance of the operations of intubation and extubation in order that no injury may be done to the larynx—all of these are preventive measures.

If, however, the case has developed into a chronic tube case, the symptoms that I have given will generally enable us to recognize to what group of cases it belongs. Whether the stenosis be due to decubitus with swelling, decubitus followed by cicatricial contracture, decubitus with paralysis of the vocal cords, or to a complication of these conditions. Having thus determined the pathogenesis of the stenosis in a given case, a matter not always possible with absolute certainty, but frequently possible to an extent that is of practical utility, then the case should be treated from a rational standpoint. Thus, when cicatricial stenosis is present, persistent intubation with a tube large enough to pass through the strictured larynx without difficulty, and yet not small enough to be expelled by the patient (autoextubation), is most apt to be successful. Such reintubation should be done at not too frequent intervals. In the Willard Parker service the resident physician has been accustomed to change the tubes every three or four weeks, giving a preliminary dose of morphine as described above. At the suggestion of Dr. O'Dwyer, to me in a case seen by him, some years ago, the tubes used for such cases were coated with astringent ointments, or a gelatin coating containing an astringent, we did not find that such cases made more rapid progress than those treated with the simple tube. The use of the tube must be continued until the patient can get along without it, which may be after a few months or a few years. But persistent intubation made at such intervals will cure most of the cases belonging to this group. Cases of paralysis of the vocal cords due to pressure on the recurrent laryngeal nerve, without cicatricial stricture are best treated by intubating with either a larger tube than the age of the patient requires, or by a tube proper for the patient but with an increased width of retention swell.

In the latter case the autoextubation is sought to be prevented by increasing the width of the retention swell. This, however, is frequently inefficacious. When, however, a larger tube than proper for the age is used the lower end of the tube is grasped by the cricoid ring and autoextubation is prevented, especially is this true in cases in which there is present, in addition to the vocal-cord paralysis a cicatricial stenosis. If the method of increasing the retention swell be used, this tube should be made with retention swell nearer to the neck of the tube than is the case in the normal tube. The object of this is to diminish the pressure of the larger retention swell upon the larynx at the cricoid cartilage. Under any circumstances in these cases of paralysis of the vocal cords in chronic tube cases, with or without stricture, the prognosis is bad. Cases that recover are cases in which the paralysis is temporary and the stricture was the element that required treatment. Sooner or later, many cases of this kind require tracheotomy to prevent death from asphyxia following an attack of autoextubation, and, as I have already stated, after such tracheotomy, atresia of the larynx, more or less general, occurs. Indeed, were it not for the occurrence of atresia of the larynx, after tracheotomy in these chronic tube cases, we would be disposed to advise tracheotomy in many of them to avoid the long-continued treatment by persistent intubation. The certainty of atresia of the larynx following the tracheotomy leads me to advise avoiding the latter in all cases save those in which the frequent autoextubations warn against reliance upon the tube for the prevention of asphyxia.

For atresia of the larynx, the treatment is purely surgical. It is in such work that Glueck, König, Gersuny, and Föderl have distinguished themselves.

It consists, in brief, in, first, a tracheotomy with dilatation of the stricture and divulsion of a limited atresia, followed by systematic dilatation. Second, laryngofissure with splitting of the stricture mucous membrane and dilatation or resection of mucous membrane, replacing this by Thiersch grafts. The laryngofissure should be left open and the larynx packed. When the grafts have been successful a secondary closure of the larynx can be done. Third, resection of the strictured larynx and low upper tracheal rings, uniting the trachea with the upper part of the larynx, so well followed by Glueck in laryngeal diphtheria, etc.

In all of these cases, however brilliant the surgical procedure, it should not be done if persistent intubation will cure the case.

In this view I am glad to have the support of V. Ritter of Prague, although he uses tubes diminishing in size during his persistent tubage. (Zur Kentniss der Atresia Laryngis post intubationem. *Archiv für Kinderheilkunde*, 32, Bd. I and II, H. 1901.)

Our cases in the hospital have been treated by persistent intubation, as I have already stated. Of the fourteen cases of which I write, five have died, seven have been discharged cured, six up to the time Dr. Bryant had tabulated the cases and one since. Of those that have died, one, C. S., was discharged as cured of prolonged intubation. Outside of the hospital she developed sudden stenosis. An attempt was made by a physician in her home to intubate—unsuccessful. She was sent into the hospital moribund. Died December 5, 1902. Autopsy showed traumatism of the larynx and stenosis, due to cicatricial contracture after decubitus, with ulceration. This cicatricial stricture almost completely obliterated the larynx.

Thus two cases of this series here reported are still under treatment.

923 Madison Avenue.

**The Treatment of Fibromata and the Prevention of Neoplasms by Means of Physicotherapy.**—J. Rivière says that electrotherapy marks out a vast improvement in the cure of fibromata. But Apostoli and his followers have, perhaps, been too one-sided in their advocacy of electrolysis alone, and at times somewhat unwise in their use of too high intensities. The author prefers what he calls physicotherapy—hydroelectric baths with frictions with the horsehair skin glove and soap, thus securing a scraping of the skin and the removal of the dead epidermis and also of the toxins and microbes it contains, the elimination of waste matter, and of organic poisons, and restoration of general nutrition. Carbonic-acid-gas baths create a healthy elimination through the skin, check the swelling processes of the fibromata of the uterus, and stimulate and regulate organic functions. Faradic currents, monopolar or bipolar high-frequency currents, and vibratory massage are a powerful help in the treatment of these growths by continuous currents. Treatment by physical agencies, by electricity in particular, restores general and local nutrition, has a decongestive local action, depurative in general, and anti-neoplastic in particular. It is, therefore, a rational and scientific medication, free from danger, and enabling us to avoid more or less dangerous operations. Take prompt action so as to prevent epithelial hyperplasia and sclerosis, ureteral enlargement, nephritis and other complications, do not attempt to replace surgery by destructive electrotherapy.—*Annals of Physicotherapy.*

# TWO CASES OF CONGENITAL ELEVATION OF THE SHOULDER, WITH A REVIEW OF THE REPORTED CASES.

By RUSSELL A. HIBBS, M.D.,

SURGEON-IN-CHIEF OF THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL;

AND

H. CORRELL-LOEWENSTEIN, M.D.,

ATTENDING PHYSICIAN TO THE NEUROLOGICAL DEPARTMENT OF THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL.

Case 1.—Harvey B., thirty-two years old, of German parentage, came to the New York Orthopædic Dispensary and Hospital in January, 1902, on account of a painful flat-foot. Incidentally, an elevation of the left shoulder was noticed and afterward carefully studied.

Father and mother have always been well and did not suffer from any deformity, nor does the patient know of any anomalies in the families of his parents. However, all of his brothers and sisters seem to be more or less defective. One sister who died of typhus at the age of fourteen years, had never been able to walk without the aid of crutches, and, to quote the patient, "she did not have the use of one leg." Another sister who is living, is always troubled with dyspepsia and nervousness. The only brother, a butcher by trade, had to have a kidney removed. He is a tall and well-built man, who now appears to be in good health.

The patient has been since birth the subject of a valvular heart disease, which forbade any very active occupation. He studied music and acquired considerable skill as a pianist, showing that all finer movements of the hand and arm, as well as their coördination, were good. At the age of eighteen years he had a stroke of apoplexy which, while it seriously impaired his memory, did not affect his muscular power. When he was about eight or nine years old his parents noticed that he had "a lump" on his back, and that his left shoulder was higher than the right. A surgeon devised a brace for him, which he wore for several years without deriving any benefit from it. Most of this history was confirmed by older brother.

The left shoulder line is considerably changed. It appears shorter, resembling very much a torticollis. On examination we find that the left scapula is dislocated upward, so that its inferior angle is four inches higher than that of the right one (see the illustration). Moreover, it is found that the left scapula is held in this elevated position by a triangular tumor, which on closer examination with *x*-rays proved to be an osseous bridge. This bridge is continuous with the middle portion of the median border of the scapula, while the apex articulates with the base of the spinous process of the seventh cervical vertebra. The bony bridge is 3½ inches wide at its connection with the scapula, and 5½ inches long from its inferior angle to the vertebral articulation. The spinous processes of the seventh cervical, and two first dorsal vertebræ, are pushed to the right and seem to be fused, forming a sharply projecting mass. The skiagraph clearly shows the bony bridge and its articulation, but does not bring out the fusion of the spinous processes, although this condition is very evident to the examining hand. There is a marked scoliosis, the first curve to the right, starting at the sixth cervical and including the fourth dorsal vertebra, and a compensatory curve to the left, in the lumbar region. Both scapulæ, that is to say their inferior angles, are equidistant from the spine. The left arm is two inches shorter than the right. No other deformities are noticed.

The development of all muscles of the left shoulder—girdle and arm is slightly less than that of the right side. The thickness at the posterior part of the neck being solely due to the triangular piece of bone and not to an hypertrophy of muscle.

The electrical reaction of all the muscles under consideration is normal, both to faradism and galvanism.

The scapula is articulating with the last cervical vertebra by means of a pivot joint, hence, it can move only around a fixed point, like a pendulum to and from the spine, and in doing so is describing part of an arc of a circle. But the scapula cannot be raised, depressed or rotated independently. All active movements of the arm can be executed, except elevation of the arm beyond the horizontal, which latter movement is impossible. Passive motion is free in every direction.

Case II.—Eli L. came to the New York Orthopædic Dispensary and Hospital to receive treatment for his shoulder and right arm, which he was unable to raise beyond a horizontal line. This condition was noticed immediately after birth, which had been difficult, and in which instruments were used. For the first few days of his life, so his mother says, the child seemed more or less unconscious and blood oozed from his ears. The appearance of the boy is that of one suffering from torticollis (Fig. 3). On closer examination the right scapula is found considerably higher than the left (1¾ inches) and its axis changed, the inferior angle pointing outward instead of downward. The right clavicle is one inch shorter than the left and its curves are more pronounced. The right arm is two inches shorter than the left. The supraspinatus, infraspinatus, biceps and pectoralis major are hypertrophied, and the head of the humerus is pressed tightly in the glenoid cavity, giving the appearance of a complete ankylosis. The deltoid is poorly developed, likewise the triceps and muscles of the forearm and hand. The hand habitually falls in a position of hyperextension. The upper portion of the trapezius is normal in size, the lower appears poorly developed, lacking in substance. The rhomboidei are below normal in volume.

In all the muscles, including those which appear atrophied, the reaction to electricity is exaggerated.

Active motions of the arm, though voluntary control is impaired, can be carried out fairly well except elevation beyond 75°. Passively the right arm can be elevated as well as the left. But with any motion, active or passive, the humerus carries the scapula along in every direction, due to the apparent ankylosis previously described. On manipulation, this ankylosis can be overcome, being solely caused by the spastic condition of the muscles.

On reading the description of these two cases, while the similarity in appearance is striking, the underlying conditions and etiology easily divide them into two different types of cases.

After a very careful study of the reported cases—sixty-three in all, including ours—a classification forces itself on us, as follows:

We include within this number five cases which have previously been reported by different surgeons under the title of "Defect of the Pectoral Muscle," because in all these cases, one of the most striking features was the elevation of the shoulder.

*Classification.*—Class I.—Cases with a bony bridge between the scapula and vertebral column.

Case 1—Willett and Walsham (1880, London), woman, thirty-one years old, with very marked deformities of skeleton (specimen preserved in St. Bartholomew's Hospital Museum, London). Case 2—Willett and Walsham, child, eight years old. Operation, triangular piece of bone. Case 3—Sainton, man twenty-six years old, who had in addition several other deformities (called "supernumerary

bone"). Case 4—Hutchinson, child a few months old, with spina bifida in cervical region in addition. Specimen shown before Pathological Society, London. Case 5—Kirmisson (possibly), boy six months old, scapula seems tied to vertebral column by osseous outgrowth. Cases 6 and 7—Rager, boy about five years old. Hernia, etc., in addition. Cases 8 and 9—Wilson and Torrance, bony bridges removed. Case 10—Goldthwaite and Painter, bony bridges removed. Case 11—Kausch (his third case, probably). (In same margin). Case 12—Hoedlmoser (boy twelve years old), probably. Case 13—Hibbs and Loewenstein skiagraph.

CLASS II.—Cases with an absolute absence of one or more muscles forming the shoulder girdle.

Case 1—Kaiser, pectoralis muscle missing. Case 2—Kalischer, pectoralis major missing. Case 3—Pren, pectoralis major missing. Case 4—Pulawski, several ribs and muscles missing. Case 5—Schlesinger, costal portion of pectoralis missing.

CLASS III.—Cases with a long and turned over supraspinous portion of scapula.

Case 1—Sand. Case reported in 1888, operated,

mproved. Cases 2, 3, and 4—Koelliker. Case 5—Honsell, double-sided. Case 6—Milo, double-sided. Case 7—Kirmisson and Jouon double-sided. Case 8—Hoffa. Cases 9 and 10—Tilanus. Case 11—Froehlich (was painful when working), operated, cured. Case 12—Mohr, double-sided (large amount of amniotic fluid and hands held habitually on back). Case 13—Goldthwait and Painter.

CLASS IV.—Cases without bony overgrowth, the scapula normal or smaller, with shorter or otherwise defective muscles. To this class belongs:

Case 1—McBurney's 1888, short muscles. Case 2—Kreke. Cases 3 and 4—Schlanze. Cases 5 and 6—Kirmisson. Cases 7, 8, 9, and 10—Sprengel (1891). Case 11—Monier, muscles contracted. Cases 12 and 13—Beely. Cases 14 and 15—Pischinger. Case 16—P. Gitsch. Case 17—Wolffheim, whole shoulder-girdle smaller. Case 18—Tilanus (his second case). Cases 19 and 20—Perman. Case 21—Tilmann. Case 22—Wiesinger. Case 23—Rager's first case. Case 24—Pankow, double-sided. Cases 25, 26, 27, and 28—Kausch, lower portion of trapezius atrophied. Case 29—Eulenburg. Case 30—Virden, states no exostosis present. Case 31—Nové-Josserand, shoulder-blade smaller. Case 32—Hibbs and Loewenstein.

In 1880 Willet and Walsham of London published a paper entitled "An account of the Dissection of the Parts Removed after Death from the Body of a Woman, the Subject of Congenital Malformation of the Spinal Column, Bony Thorax, and Left Scapular Arch, with Remarks on the Probable Nature of the Defects in Development Producing the Deformities."

In the specimen described, the most striking feature was a triangular piece of bone attached to the middle of the vertebral border of the scapula, extending upward and inward and articulating by means of a pivot-joint with the spinous process of the seventh cervical vertebra.

After a careful and most scientific study, the authors advance three different hypotheses as to the etiology of this anomaly: (1) That the process of bone was formed in connection with the vertebræ and afterward became ankylosed to the scapula. (2) That it was originally a scapular element and secondarily became fused to the spine. (3) That it was formed independently of the spine and scapula.

Shortly after the first case, Willet and Walsham published a second case, which was identically the same, as far as the triangular bony bridge was concerned. The "supernumerary bone" was removed by operation with perfect results. The evidence in the cases described seems to be in favor of the scapular element, and the bony bridge is probably connected with an overgrowth of the epiphyses which normally exist along the posterior border of the scapula. Willet and Walsham go on to say that "the bone may perhaps be homologous to the suprascapular of some of the lower vertebra. It certainly bears a superficial resemblance to that of the frog and toad, in which creatures, however, it is not united to the spine. As far as we know, the only vertebrate in which the suprascapular is so united, are the skate tribe." If this be so, it would surely show a retroversion to a lower type of development.

Kirmisson, in reporting a similar case, regards it as a primary malformation of the scapula.

Our first case seems to be identical with those reported by Willet and Walsham: the triangular piece of bone is continuous with the scapula and it articulates with the seventh cervical vertebra, by a pivot-joint.

J. Hutchinson, Jr., in 1894, presented a specimen before the pathological Society in London, showing a bony connection between the scapula and the cervical spine. He refers to the cases described by Willet and Walsham, and says his is the third case reported. "The deformity of the left upper limb was found in an infant but a few months old, the top of the scapula being almost immediately under the occiput, nor could it be materially depressed. The reason of this malposition of the left scapula was made out to be a band or flattened process of bone, extending from the cervical spinous processes to the upper end of the vertebral border of the scapula, with which it articulated, allowing a slight amount of movement at a hinge-joint."

No other deformities were noticed, and there was

no lateral curvature of the spine. Hutchinson goes on to describe the specimen which he was fortunate enough to secure shortly afterward. "There is nothing noteworthy to be recorded of the muscles of the neck, several of which were connected with the outgrowth of bone, the rhomboid muscles were present, and had their usual attachments. The arches of the third, fourth, fifth, and sixth cervical vertebræ were not united by bone in the median line; on the other hand, the left posterior laminæ of the fourth, fifth, and sixth cervical vertebræ had, to a great extent, fused together. From the fourth left posterior lamina (connected to it by a firm cartilaginous junction) grew downward and backward a rounded piece of bone, which was reinforced by similar processes from the three lower vertebræ, the whole uniting into a bony mass, which curved to the left, and was joined by cartilage only to the upper end of the vertebral border of the scapula. It should be noted that the latter presented a broad cartilaginous portion, in which the epiphyses for the spinal border would have been no doubt later developed." From the careful study of this specimen he comes to the conclusion, "That the abnormal bone is due to an irregular and redundant ossification of some of the cervical vertebræ, which has united by cartilage, or articulated with the scapula."

Hutchinson quotes Professor Cleland of Glasgow to be of the same opinion, that the added element, in the case under consideration is vertebral.

With Hutchinson, Wilson and Torrance regard it as a vertebral overgrowth, etc. In their two cases the pivot-joint was developed at the scapular extremity of the bony bridge, instead of at the spinal. They removed the bony bridges with perfect results, restoring, in both cases, normal position and mobility to the scapula. In their conclusion Wilson and Torrance say: "The characteristics of both specimens render justifiable the theory that there has been an extra center of ossification for a spinous process, and this has been pushed or placed beyond the normal center for the process of the seventh cervical vertebra, though this does not account for the fact that in both cases there was firm articulation with the scapula."

These cases answer to the first hypothesis of Willet and Walsham.

Sainton believes it to be a supernumerary bone, likewise Drs. Goldthwaite and Painter, who operated upon their case. The interesting feature of the latter case was a joint developed at either extremity of the bony bridge.

The above cases seem to demonstrate the third theory advanced by Willet and Walsham.

In our case the existence of the bony bridge and its continuity with the scapula is proven beyond doubt by the skiagraph. An operation was not advised on account of the patient's age.

As far as the etiology goes, we think the deformity in our case is due to an epiphysial overgrowth (suprascapular), consequently a return to a lower type, and we think we are justified in this belief, since the patient shows other stigmata of degeneration, heart lesion, flat-feet, etc.

The deformity is of developmental origin and certainly of an early date, probably not later than the sixth or seventh week.

The description Dr. Kausch gives of his third case induces us to place it among our first class. A revision of the case under this light would be of great value.

The second class of cases is due to a congenital lack of one or more muscles. That the defect in the quoted cases is congenital, seems reasonable, since in all of them we find one or more ribs wanting, or other grave signs of degeneration. It is not quite plausible that a mere lack of amniotic fluid should be the cause of such grave defects, but rather a faulty differentiation of the mesoblast, leaving out the necessary centers for the tissues wanting.

The third class of cases, due to the curved and possibly enlarged condition of the supraspinous portion of the scapula, again represents a very clearly-cut group of cases, which show a mechanical interference as the factor of disturbance. In the cases in which this supraspinous process was excised (Sand's, Hoffa's, Froehlich's, etc.) the dislocation of the scapula was reduced and all normal functions restored. Sprengel's theory, that the deformity is an outcome of intra-uterine pressure due to a lack of amniotic fluid, is more than likely.

It is interesting to hear from Professor Chievitz of Copenhagen that a high position of the scapula is a fetal condition. The pressure on the elevated scapula exerting itself on the supraspinous portion, which possibly reaches beyond any support from below, bent it forward, and the resulting hook-like condition of the supraspinous portion prevented the descent of the scapula at the proper time.

Mohr states definitely that in his double-sided case, a very large amount of amniotic fluid was present. The patient had the habit of carrying his hands on his back. Here, the large amount of fluid may have induced, in its turn, an increased intra-uterine pressure and brought about the same result.

The fourth class of cases is less definite in appearance, and of more obscure origin.

A number of different causes seem to underlie.

In some cases muscles are contracted and hypertrophied. In others, atrophied, or partly lacking (Kausch).

In one case the whole shoulder girdle is small (Wolffheim). In some a grating noise is produced on movement of the shoulder (Myer).

That this difference in the cases has been appreciated is clearly shown by the number of etiological theories advanced in their connection.

Professor Meyer of Copenhagen thinks that in some cases the elevation is the result of a loosening of the epiphysis of the upper arm.

Professor Bloch of Copenhagen thinks that in some cases it is due to a poliomyelitis anterior acute or eventually to a cerebral affection intra-uterine.

Schlange believes that membranous adhesions caused it.

McBurney believes it to be the result of an accident at birth, and Hutchinson an intra-uterine rachitis.

Kaush, quoting Damsch, believes it to be a dystrophy which soon became stationary. In this connection it is interesting to learn that Goldthwaite and Painter, on operating upon their first case, found the trapezius and rhomboid, which they divided, contained little muscular fiber, and were represented largely by fibrous tissue.

It is evident that the fourth group of cases represented different conditions which have not been studied extensively enough, and that, most likely, a number of them are not true cases of congenital elevation, some of them similar to our second case. The three first groups, however, are so distinct in their anatomical features that there is no doubt about their congenital origin.

We disregarded Rager's classification, since we did not see what influence the "change of axis" had upon the cases. The axis change, to our mind, is dependent wholly on the traction of muscles, and may depend on the existence of some mechanical interference, but is not in itself the cause of the deformity.

*Treatment.*—In the first and third classes the only

rational course is to resect the bony bridge or bent-forward piece of bone. In the second class we have to content ourselves with orthopedic appliances, to press the shoulder down, and so substitute the missing depressors of the shoulder. The fourth class most likely will have to be treated orthopedically, by apparatus, massage, exercise, electricity and, in selected cases, by the knife.

**Prognosis in Chronic Suppurative Otitis.**—Asking the questions (1) what is the future as regards the cure of the patient suffering from chronic otorrhœa? and (2) what chance has he for the relief of his symptoms along conservative lines of treatment, and what risk is he running of sooner or later suffering from fatal complications? T. J. Harris replies as follows: (1) Chronic otorrhœa in a large percentage of cases is amenable to suitable medicinal treatment. (2) In addition to proper attention to disease of a general character and to the nasopharynx, peroxide of hydrogen, with or without formalin solution, gives the test results, all minor operative procedures, of course, first being attended to when necessary. (3) The results of such treatment are in a good number of cases permanent. (4) The risk of an uncured otorrhœa with good drainage is relatively very small ($\frac{1}{2}$ of $\frac{1}{3}$ per cent. fatalities). (5) Medicinal treatment failing, after a suitable interval of time, the danger of fatal complications in absence of all symptoms should be laid before the patient and the promise of relief by operation stated. (6) Where there is no good reason to the contrary, such as intracranial or mastoid complications, the intratympanic method by ossiculectomy should be preferred, because: its results as regards cure are equally good; the risk of loss of hearing is vastly less; the danger of unpleasant sequelæ, such as facial palsy, is avoided; the possibility of prolonged after-treatment is obviated. (7) The radical operation is not without risk of life. (8) Where ossiculectomy fails or mastoid or other symptoms exist pointing to extension of the disease into the bone, it then becomes the suitable and valuable method of relief. (9) The protecting and assisting power of nature is never to be lost sight of.—*Archives of Otology.*

# LIFE AND ITS PHYSICAL BASIS.

By AXEL E. GIBSON, M.D.,

LOS ANGELES, CAL.

Through the tube of my microscope I am watching the development of a speck of protoplasm. Strange possibilities lie dormant in that semi-fluid globule. Let a moderate supply of warmth reach its watery cradle, and the plastic matter undergoes changes so rapid and yet so steady and purpose-like in their succession, that one can compare them to those operated by a skilled modeller upon a formless lump of clay. As with an invisible trowel the mass is divided into smaller and smaller portions, until it is reduced to an aggregation of granules—not too large to build withal the finest fabrics of the nascent organism. And then it is as if a delicate finger traced out the line to be occupied by the coming spinal column and moulded the contour of the body: pinching up the head at one end, the tail at the other, and fashioning flank and limb into due proportion in so artistic a way that after watching the process one is almost involuntarily possessed by the notion that some more subtle aid to vision than the chromatic would show the hidden artist, with his plan before him, striving with skilful manipulation to perfect his work. THOMAS HUXLEY, "Lay Sermons."

IT is to Professor Huxley we are indebted for the equally rhetorical and scientific term "Physical Basis of Life" applied to the primitive life-substance which, as early as 1846, by Hugo von Mahl, had been defined as *protoplasm*, from *protos* "first" and *plasma* "formed substance."

By protoplasm we understand that unorganized indeterminable, unit-essence from which the numberless forms of manifested existence draw their vitalizing fluid. In its gelatinous quivering mass, the powerful modern magnifying lens discloses a blurred, unsteady figure, the *recticulum*, in which lie imbedded a number of deeply staining granules—the *gemmules of* Darwin; *plastidules of Haeckel*; *physiological units* of Spencer, and *Microsomes* of our histological textbooks. Furthermore we find the centresome with its *centrosphere*—an impermanent body, which first appears at the moment of cell-division and is formed *de novo* in each process.

In the center of a limited mass of protoplasm floats the *nucleus*, a sharply defined zone, composed of a number of more or less hypothetical substances, among which phosphoric or nucleic acid exhibits a dominant action, Like the protoplasm *per se*, the nucleus presents a reticulum with its corresponding granules, the chromatins, and a sustaining net work—the *linin*. From the interaction between the protoplasmic elements and the nucleus springs the whole mass of numberless terrestrial existences.

Hence, as an active element, proptoplasm is inseparable from the conception of cell and cell-division. The single cell has been defined as "a nucleated clump of protoplasm, with or without a limiting cell-wall." Yet, under cover of this insignificant-looking "clump of protoplasm" undreamed of forces and possibilities are held in abeyance. In *mitosis*, or the process of cell-division, some hints are given as to the marvelous energies that lie concealed behind this screen of almost structureless substance. The nucleus constitutes the gateway through which the unmanifested rises into the manifested. The first attribute of the nucleus is manifested in its power of engendering the act of cell-division. Through a series of scene-shifting or *phases*, respectively *prophases*, *metaphases*, *anaphases* and *telephases*, the cell with its nucleus undergoes a cycle of structural changes, subsequently appearing in the nucleus, centrosome, and cytoplasm. It is, however, in the centrosome—the minute granule situated in close proximity to the nucleus, that the first sign of proliferation is made visible. Its behavior reveals the presence of liberated electro-vital energies. *Mitosis* commences by a spontaneous division of the centrosome into two equal parts, each forming a temporary pole. Between these two polar bodies the intercellular substances are grouped into the figure of a spindle, which, during the entire process, is maintained in a state of rapid revolution.

During the entire mitosis an unceasing exchange of electro-vital energy seems to take place between the two poles, giving to them the appearance of radiating light; stimulated by the influence of this polar radiation, the nucleus swells, looses its consistency and gradually breaks up, while the fragments of its framework—the chromosomes—are taken up by the whirling centrosomes or polar bodies, and subsequently polarized into two crown-like figures, which arrange themselves on opposite sides of the cell. The process of the mitosis then proceeds through a series of startling metamorphoses, which must be seen and studied in order to be appreciated; the two figures gradually condensing and fashioning themselves into perfect duplications of the original cell body.

The division and multiplication of the single cell leads to the formation of structural tissues. Gradually the ever-increasing number of cells, under the ensuing pressure of environment, are forced to evolve types and properties of specialization. The contents of the proliferating cell differentiates into three determinable layers, thereby inaugurating a stage of existence which, to-day, has its living representative in the *hydra* or fresh-water polyp. In this polyp we discover a type in which the single cell of *Amœba proteus* has unfolded into a figure of a hollow tube. In this vegetative tube the outer covering, the *ectoderm*, forms the basis for sensation; the inner or under covering, the *endodern* foreshadows the tissues and viscera of assimilation, while the intra-membranal layer, the *mesoderm*—formed between the inner and outer layers through the invagination of the tube, presents the substratum for the grand vascular and structural system of the future vertebrates. Thus from the inner layer springs the digestive tract with its surface of epithelial glands; from the middle grows the bones, blood, muscle, and connective tissue; while from the outer emerges the skin, membranes, epidermal appendages, and the entire ramification of the nervous system.

The life-history of any organism is in its essential features the life-history of the single cell. The origin of species and the ascent of man, can be plainly traced in the protoplasmic changes wrought in the unfoldment, of the single cell. For the cell is the first organism in the series of organic evolution, the first figure impressed upon the plastic material of the elemental world. Its form and constitution vaguely, though unmistakably, forshadows the "portraiture of things to be." For evolution does not mean generation, nor much less creation, but rather the unfoldment, through formative processes, of powers and energies uncreated and indestructible, and already present in the single cell. The *Amœba proteus* and *vorticella nebulifera*, the simplest forms of animal life yet described by the armed eye of science, possess in potentiality every function exhibited in their most accomplished descendents. The Amœba, while consisting of a single naked cell, is nevertheless a complete organism, possessing in its nucleus water-vacuoles, contractile vacuoles, food-vacuoles and limiting membranes, the complete apparatus for the highest order of vegetative existence. Through this apparatus, the little creature is enabled to perform, rudimentarily, the whole range of physiological activities subsequently developed in the higher types of evolution. Exposed to the lynx-eye of the microscope, this little creature is seen to exhibit not only responses to external

stimuli, but likewise feats of spontaneous, independent movement. Minute, tongue-like projections—*pseudopodia*—are extended from its surface to serve as means of locomotion. And as function is ever seen to precede structure, so the function of independent spontaneous movement must be regarded as an inherent power of protoplasm. Subjected to suitable environment, this function from latency, is brought into structural operation, followed by the subsequent evolution of organs of locomotion.

Again, if amœba while moving across the slide of the microscope should encounter some food-yielding substance, the little organism at once surrounds the object and engulfs it in its fluidic mass. In a similar way the useless substances which once served as stimuli to the ingestive functions of the little entity are properly eliminated as excreta. In scientific parlance this attribute of the cell, of ingesting and assimilating nourishment, is known as metabolism, an attribute which must thus be conceded to have its genesis and potentiality in the undifferentiated protoplasm.

Now these three phases of the protoplasmic substance, the power to stir, or *mobility;* the power to transmit, or *conductivity;* and the power to assimilate or *metabolism*, constitute the triple-basis for the whole nervous mechanism, as it is by virtue of the sustained and harmonious co-operation of these three cell attributes that organized existence is made possible.

If for a moment we observe the career of the cell in that special phase of its development—the nervous system—we cannot escape from noticing how closely the process of its proliferation is subjected to an ever-present purposive modification. The first modification of the multiplying cell-mass aims toward the formation of a cerebrospinal axis (the stages of growth being easily verifiable in the development of the embryo) manifested in the appearance of a longitudinal groove, whose lateral edges grow up toward a midline, in which they meet and fuse together. This process transforms the groove into a tube, which a subsequent enlargement of the upper end fashions into the future human cranium; while the remainder of the tube is modified into the magnificent spinal cord with its equilateral nerve-arborizations. Hence in the single cell the whole nervous system is held in abeyance, and like a photographer's negative is developed under the influence of external adjustments through environments.

Thus it is in the cell (being a representative of the protoplasmic essence) that we have to search for the source of the vital currents which move the mechanism of the organized world. The single cell is the *sphinx* which holds in its grasp the secrets of life and death. There is not a manifestation throughout the long sliding scale of organized existence, however complex and dazzling, which has not its genesis in and through the obscure life-processes of the single cell. From its mystic, imponderable depth, the forces of evolution well up their torrents of all-embracing, all-stirring energy. The cell brings us closer than any other physical manifestation, to the mighty, all-penetrating, life-force, which Proteus-like, forever disappearing and eternally reappearing, proceeds through the guise of marvelous metamorphosis to engender ever new wonders of growth and progress. With unceasing rhythm its invisible currents sweep through the cycles of change, registering the attributes of wisdom, beauty, and power in the forms and characters of the various kingdoms of nature—liberating, dissolving, and breaking down, again to remodel, reconstruct, and reorganize. Thus while the staging or framework of the protoplasmic or cellular structures are continually breaking down and eliminated from the field of action, the result remains and is visible in the crowning edifice of evolution, the temple of man "built without the sound of nail or hammer" sending its spires of attainments to ever higher evolutionary altitudes.

This intermittent activity of protoplasm in breaking down and building up structures, constitutes the two poles or aspects of organized life. In the language of physiologic technique, the evolutionary process consists of the breaking down of a structure or its *katabolism*, its reconstruction, or *anabolism*, and the totality of the two processes, or *metabolism*.

A series of changes are wrung out from these dual forms of evolution. The resulting action may be diagrammed in the figure of two opposing stairs converging in a summit, of which the one side represents the *ascending*, the other the *descending* currents of protoplasmic energy, while the summit indicates the vital chemical field of action where the amorphous and unorganized life-stuff becomes changed into form and structure.

On these emblematical stairs the carriers of life climb up and down. Along the ascending—the anabolic—grade, rolls up the cargo of ingested and assimilated vegetative material, which after having become deposited in the formative and constructing vortex of the cell, again departs downward—the opposite—the descending of katabolic grade, freighted with the *débris* of the metabolic exchange; while finally the resulting sum-total of the process is manifested in the marvelous fabric of organized structures.

The ascending grade on this ladder of metabolic action is marked by a series of forms and substances constantly increasing in complexity as they rise toward the figurative summit, while the descending grade presents a corresponding simplification of the ensuing katabolic bodies sinking in the scale of physiologic and nutritive value from *nuclein*, *nucleic acid*, *phosphoric acid*, down the chain of the more and more devitalized *alloxuric* bodies until finally at the end of the ladder, the katabolic changes terminate in the waste products *uric acid* and *urea*—the latter being the nearest approach to physiological ashes to be found in the output of the animal-human furnace.

As the food stream passes up the physiological ascent, forcing its way through the specific vesicular membranes under the guiding influence of the selective affinity of the cells, the trophically changed molecules explode into a series of protoplasmic deposits, through which the nutritive elements become dialyzed into tissue-building energy.

The factor which regulates the dialyzing membranes in their selective affinity is contained in the principle of molecular vibration, *i. e.* in the property of *numbers*. All electro-vital action proceeds through a series of ganglionic shocks or discharges, and their number expresses the vital intensity and functional power of the cells. The ascent of life means an increased capacity of the unit—whether considered as single cell or as individual—to respond with its molecular constituency to an over-increased ratio of vibration. This relation between number and functional power has been demonstrated as actively present in every phase of organic unfoldment, functional or structural.

The whole range of world-dynamics may be said to be contained in the single cell, or its protoplasmic substratum. For the latter is not limited to organic existence—being likewise found to form a basis to the inorganic world. On the strength of recent researches, Professor von Schron of Leipsic maintains that the barriers between the organic and

inorganic kingdoms will have to be removed if an intelligible study of nature is to be made possible. His experiments have proven beyond doubt that crystals possess vital powers. He has found them capable of exhibiting the vital phenomena of "(1) individual motion; (2) structural evolution of the substance in which the crystals are constituted; (3) characteristic movements in the shape of generating and promoting vibratory waves." To this may be added that Professor Crookes as early as 1868 exhibited glycerin crystals to the members of the chemical society in London. Though the learned lecturer failed to explain the principle at work in the singular process—it being a mystery to himself—the phenomenon yet makes evident the reality of a basic identity of all substances. Or, to quote from Mr. Crookes himself: "All the endless diversities of being are bound together by a physical as well as an ideal unity. . . a unity of power or structure, as well as a unity of elemental composition."

Truly Huxley enunciated a great truth in his famous definition of protoplasm. Being the "physical basis of life," protoplasm constitutes a unit at once of structure and function. The cellular form imposed upon its homogeneous mass adds in reality nothing to its generative powers. The cell constitutes the first ascent from the protoplasmic level toward organized existence. In the cell the protoplasmic dynamo receives its first rudimentary vehicle by which to start its series of world-fashioning changes. All the cellular elements (mechanical or chemical) are more or less of hypothetical character; and it has been experimentally demonstrated that the centrosome, centrosphere, chromosome, polar bodies and the various temporary figures, appearing and disappearing in the course of cell-life, are apparently accessories and form no essential element in the process of cell-division. They serve as mere conductors or pathways in the course of externalization of the one indivisible power welling up from the protoplasmic deeps into the world of manifestation. In his recent remarkable experiments on sea-urchins, in which is shown the power of the egg to undergo the primary stages of parthenogetic development as the result of artificial chemical stimulus, Professor Loeb has rendered this character of the cell evident. He considers that fertilization itself is an "ionic" act and "the nucleus of the male cell inessential to the process as merely serving as an adjunct-stimulus in the adjustment of the proportions of the surrounding ions." By saline preparations, this daring explorer in the "dark continent" of biology, displaces with triumphant success the various structures of the cell in the process of artificial fertilization.

Never before, in all recorded history, did physical science so boldly and so successfully advance toward the solution of the great world-problem of *life*. But the great problem lies perhaps deeper than the purely *physical* science can reach. For protoplasm with all its mystery, with all its exhaustless resources of energy, is still the mere *physical basis* of life—while life itself lies infinitely deeper. To chemically dissect protoplasm and search for its veiled source of power, is certainly of great physiological value; but does it, after all, bring us really nearer an understanding of life itself? Would an examination of Beethoven's violin or piano, even if submitted to the analysis of dissection, initiate us into the mystery of musical composition, or lay bare to us the anatomy of his Ninth Symphony? And what is the "physical basis of life" but an instrument—infinitely intricate and subtle, it is true—but yet an instrument, through which vibrates, both chemically and mechanically, the unanalyzable and indefinable power of the immortal breath of life?

Hence we cannot believe that the definition of life as a mere output of nucleic and saline solution is to be considered final. While we readily grant that these elements, in furnishing suitable arrangement for the physical manifestations of life, must be regarded as indispensable factors, yet they are *conditions* merely, not *causes*. They constitute *life's* first immediate environment. For what is natural evolution but the demonstration of the progress wrought by an individualized vital principle in the substance of physical invironment. So far from the environments being the *cause* of evolution, on the contrary, they constitute its limiting *vis restantia*. In protoplasm Life encounters its first environment, followed by the infinite variety of others, ranging from the single cell through subsequent cell divisions up to ever higher and more complex forms of organized existence. Evolution may thus be called the fountain of life, inasmuch as it reveals through its organic output the scope and character of the forces at work in its vital current. And as the force, active in a fountain, by overcoming the resistance and friction of opposing environments, flings its liquid masses into cascades of towering height, is not caused by nor inherent in, the water itself, but in the influence of the surrounding atmospheric pressure, so likewise back of the protoplasmic stream—a veritable fountain of life—moves the silent, invisible substanceless essence of life itself, lifting the whole sliding-scale of elemental and organic structures up to ever higher altitudes of evolutionary fitness.

Now the immediate purpose of evolution is to demonstrate the qualities and powers latent in life. Every leaf or flower is a living, irrefutable demonstration in the vegetable kingdom, of the *beauty* of life; every rock or boulder demonstrates in the mineral kingdom the *power* of life, while every creature of the animal and human kingdom demonstrates on that plane the *intelligence* and *wisdom* of life. Existence is a school, and every form or object—animate or inanimate—constitutes an infinite equation, and an equation which sooner or later must be solved. And the solution, within the reach of all, lies in an earnest, unselfish application of one's entire nature to the phenomena and vicissitudes of life, gauged by love, and prompted by will and reason. For each problem solved in outer nature, the student will at once find a corresponding problem solved in his own personal nature, as man in himself is an epitome, not only of the past, but also of the future.

The result of such application manifests in the formation of *character* and *individuality*. And this seems to be the purpose—conscious or unconscious—which, like a guiding Ariadne-thread, leads the individual through the labyrinths of natural evolution.

"Yet I doubt not through the ages one's increasing purpose runs,
And the thoughts of men are widened by the process of the suns."

Perhaps, after all, the old statement of the mystic Carpenter of Galilee, that "he who lives the life shall know the doctrine" is not without its scientific value.

---

**A Lugubrious Missive.**—An ex-patient of the Bristol Royal Infirmary, dis atisfied with the treatment he had received, cut off one of his ears and sent it to the medical officer, with a letter couched in abusive terms. He was subsequently taken before a magistrate with a view of ascertaining his mental condition, but the result was a verdict of sanity. Under ordinary circumstances self-mutilation would be accepted as *primâ facie* evidence of insanity, but the Forest-of-Dean magistrates are apparently extra-particular.—*Medical Press.*

# A SIGNAL TEST FOR COLOR-BLINDNESS.*

By PERCY FRIDENBERG, M.D.,
NEW YORK.
ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY, ETC.

It is about a generation ago that Holmgren devoted himself to applying widely and popularizing the wool-test for the detection of color-blindness, which is now generally known by his name, but which was originated and first employed by Seebeck. The popularity of this method is well shown by its numerous modifications. Thus we have wool-tests of Thomson, Williams, Oliver, Jennings, pseudo-isochromatic wools of Donders, Reuss' color-tables, the embroidery patterns of Cohn, colored cylinders of Badal, Mauthner's colored powders in flasks, and others. Holmgren's test, as well as its varieties, use as test-colors red, green, and pink of low intensity and saturation, and as confusion-skeins various combinations of these and of other colors, notably blue, yellow, orange, and purple, with different amounts of gray, so as to produce a series of tints or shades. The subject is required to match similar shades, placing them with the test-skeins which they are judged to resemble, without naming the colors or being required to indicate them on their being named.

The test aims at picking out two classes of men, the red-blind and green-blind, so called on account of their inability to distinguish the red element in such color combinations as purple (red + blue), brown (red + black), orange (red + yellow), particularly when obscured by the addition of much white, as in tints of coffee color, lavender, etc., and the confusion of such combinations with those in which green takes the place of red, namely blue-green, dark green, yellow-green, sage. The advantages of this method have long been recognized. Allowing the subject to select the skeins or colored objects at his ease, and to match the test-colors, and then passing final judgment on his selection, allows a number to be examined at a time, does away with the sources of error and misleading factors incidental to a questioning examination, eliminates the factor of defective color vocabulary, and the possibility of naming a color without differentiating it, or *vice versa*, so making the test to a certain degree objective. Besides this, we are enabled to detect slighter disturbances of color-sense, which, under ordinary circumstances, using very brilliant and pure colors, might not be made evident, and would escape detection. Red and green, the colors of greatest practical importance, as they are used on railroads and shipping for urgent signals, whose disregard or confusion may cause, as they undoubtedly have caused, loss of life and fearful accidents, may, under favorable circumstances, be distinguished by a color-defective whose perception for differences of shading, of tint, is abnormally, we may say vicariously, acute, by appearing to him of different shades, that is, one darker than the other. With variously shaded test-colors this means of identification is removed, and the perception of color value alone is made the guide to recognition, and so the crux of the test. In spite of the delicacy of the Holmgren test, perhaps on that account, its practical value has been impugned, and objections have, from time to time, been raised on various scores, many of them inadequate, to confusion-tests as a class.

Thus it has been claimed that it is unfair to subject engineers and pilots to the test of matching colors; that their occupation and the demands of safety in transportation require only the recognition of the identity and the naming of a few colored lights, all of them brilliant and pure, and not the comparison and judgment of similarity between a thousand and one skeins of wool or spools of silk, colored faded pink, dirty green, rusty browns, café-au-lait, yellow-gray, and other æsthetic but badly defined hues.

Although this contention is not based on any scientifically valid reasoning—for it could be shown by an analysis of the function of color-vision, which would carry us too far from our immediate topic, that just such delicate and apparently irrelevant means are required to insure the detection of any case of color-blindness and not only that of the most flagrant—it is nevertheless a fact that conditions so different from those of actual service do militate against unquestioning adoption of the test by causing a certain attitude of suspicion toward results obtained by its use alone and of sentimental opposition to it as taking an unfair advantage of the subject of examination.

On the other hand, there is reason to believe that a certain, although in all probability a very small, percentage of the color-defective are able, by their unusual sensitiveness to slight differences of light and shade, an increased acuity which is at once the product of, and, to some extent at least, a compensation for lacking color-perception, and by the detection of irregularities of surface and texture, which escape the normal eye, to avoid confusing certain colors when they have been used to dye the Holmgren-Seebeck wools or similar fabrics.* At a recent meeting of the British Ophthalmological Society, Edridge-Green called attention to the facts, pointed out by him some years before as a member of the Committee on International Signal-Codes, that the Government tests for color-blindness are still insufficient, and the enforcement of regulations too lax. His prediction had been fulfilled that if color-names were ignored in the Board of Trade tests, and reliance placed solely on the Holmgren system of matching colors, normal-sighted persons would be rejected. He emphasized the fact that an engine-driver or sailor had to name a light when he saw it, and not to match it. Scripture sums up the objections to the Holmgren test, as follows: The requirement of reliability is not met. In the first place there are many cases of rejection for color-blindness which later examination proves to have been unjustified. There are also many cases of color-blindness discovered after the person has passed the test; these are regularly treated as cases of "acquired" color-blindness without the certainty that they are not sometimes cases of overlooked color-blindness.

On the other hand, railway and marine surgeons who use a test with colored glasses in addition to the wool-test, constantly report the discovery of cases by the one which have successfully passed the other. Furthermore, the test-objects and the conditions under which they are judged do not conform to actual service. In practice the railway man or pilot is never required to put into a pile all the objects that resemble a certain sample, but to decide for himself which of the lights he sees are red, green, and white. An ideal test would consist of an immense number of such lights under all the variations of brightness, distance, fog, etc. The person tested should be required to name the objects. This is just what he does in thinking about the lights he sees when at work; he decides that this one is "red," that one is "green," etc. The judgment of the likeness or unlikeness of colored objects is an utterly

*Presented at the New York Academy of Medicine, Section on Ophthalmology, January 19, 1903.

*V. C. Devereux Marshall, Mauthner, Scripture.

different matter and involves a different form of mental activity. Great trouble and uncertainty arise in the wool-test because it demands a different form of judgment from that to which the men have been accustomed.

Finally, several colors should be presented simultaneously for comparison.† In practice the person sees several lights together; he compares them and decides on their colors. The secret of the past success of the Holmgren test over the tests of the Donders form with colored glasses lies in its use of the principles of comparison. An ideal test would combine this principle with those in which the Holmgren test fails.

However opinions may vary as to the entire reliability of the Holmgren test, there is undoubtedly a consensus that it should be supplemented by a test with signal lanterns capable of demonstration to the subject, and, what is equally important, to disinterested persons. A perfect test would require not only signals similar in color, size, and position, but also the variations in all these factors corresponding to the vicissitudes of illumination, distance, and atmospheric conditions. If locomotive engineers were required only to recognize a single brilliant red light near by, on a clear night, or a clean red flag on a bright day, the matter would be greatly simplified. On the contrary, they must recognize, and that without an instant's hesitation, red, green, blue, white, and occasionally purple or yellow lights, whether obscured by mist and passing steam, blurred by rain, or darkened and changed by smoke and fog, at daybreak or dusk when they pale in the twilight.

The lantern which I have devised is intended to reproduce service conditions on a diminished scale. The colored glass used for the signals is made of standard red, green, blue, yellow, and purple as supplied for switch-lights on one of the largest railroad systems of the country. The lantern is in the form of an asbestos chimney like those used for retinoscopy. It may be lit up by a candle, or, preferably, slipped over the glass chimney of an argand-burner or the bulb of the incandescent electric-light, and used in the darkroom. In view of the absence of an independent light-source the term "lantern" may seem a misnomer. I have accepted this lesser evil in preference to that of making the instrument unnecessarily complicated and hence costly. The argand-burner is always available, and may be greatly varied in intensity, so giving the changes similar to those of actual service. A disc containing apertures ranging from one to twenty-five millimeters in diameter allows quantitative variation corresponding to distance, and a series of ground and London smoke glasses produces changes like those due to smoke, fog, and snow. The testing-distance is five meters with the smallest aperture, the flame having been lowered until no radiation of white light is seen about the edge of the opening, so that the illuminated area appears clear and distinctly outlined. For quantitative tests the maximum distance for the observers—supposedly normal—eye should be determined. A spring shutter large enough to cover the twenty-five millimeter opening allows the signals to be exposed momentarily, if desired, and thus to test macular color perception.

The lantern is manufactured by E. B. Meyrowitz, to whom I am indebted for a practical embodiment of my suggestions.

114 West 126th Street.

†The last principle enunciated does not appear tenable to the writer, for while the person "sees several lights together," or rather a great many, he does not compare them, or judge them simultaneously, but "picks them up," in succession, recognizing each in time and acting on that recognition.

**The Movement and Migration of the Lymphocytes.**—G. B. Vlasson and E. K. Sepp, in summarizing the results of their observations, conclude: That the lymphocytes in consequence of the disproportion in the amount of the protoplasm and nucleus are incapable of movement, and the movement they exhibit in the form of the destruction of the cell with the preceded destruction of the nucleus can only be compared to the necrobiotic movement of portions of protoplasm without nuclei. The movements of lymphocytes observed in a drop of blood are as follows: the lymphocytes of the blood in man have a capability of amœboid movement, but only a potential one, which passes into a kinetic only under conditions unfavorable to cell life—under conditions of increased motility of the cell in a state of necrobiosis. In view of the exceptional conditions required for the occurrence of this process, the certain quick destruction during this process of the leucocytes, and the peculiarities in the motion of the lymphocytes contrary to the laws of fatigue and exhaustion, we may consider the amœboid movements of the lymphocytes, though physiological in their character, but occurring beyond the normal limits of physiological activity. The exhibition by the cell under such conditions of such an activity can not be considered as the expression of one of the normal life functions of the cell, so that, until the movements of the lymphocytes shall be proved by direct observation to occur under normal conditions, we must decide the question negatively. The same is to be said about the migration of these cells from the blood vessels during inflammatory processes, since there are no direct proofs of this in literature, and the material brought forth by some observers is so contradictory and indefinite that it can be used just as well to disprove as to prove the theory.—*Meditsinskoye Obozrenye.*

**Remarks on the Treatment of Paralysis Agitans (Parkinson's Disease.**—J. Madison Taylor states that the indications in Parkinson's disease are to overcome the growing apathy; to induce systematized return to normal activities; to use all gentle and yet forceful means to secure elasticity to the tissues, and finally to stimulate the circulation in the spinal cord by graduated pressure upon the spinal areas through which reflexly many of the fibers in the cord can be restored to function and others improved. Above all, care and patience and persistence must be forthcoming on the part of the physician, and intelligent coöperation demanded in the patient. Whether a cure can ever be attained is only to be learned by increasing experience, but the profound improvement obtained in some exceedingly severe cases, warrants the hope, and expectation, if moderate, can be at times exceeded. In so hopeless a condition these rational measures are certainly well worth a fair trial, and in the earlier stages of the disease they promise to secure abundant rewards.—*Proceedings of the Philadelphia County Medical Society.*

**Some Directions and Avenues through Which Cancer May Possibly Be Successfully Treated and Perhaps Cured.**—C. H. F. Routh calls attention to the fact that in a number of cases cancerous growths have disappeared spontaneously by exposure to the atmospheric air. The cause of the cure was undoubtedly the oxygen in the air. He reports two cases in which the application of peroxide of hydrogen induced a complete disappearance of the cancerous growth. He also speaks of the effects of vibration which have the power of hindering the growth of microorganisms, and suggests that cancerous masses be singled out, and shocks passed through them. Possibly a cure might follow. As McFayden has found that by crushing the bacterial cell it is possible to remove the contained poisonous juice, the real source of the disease, the author thinks that the method might be applied to the curing of cancer.—*Medical Press and Circular.*

## THE MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THE seventy-first annual meeting of the British Medical Association held this week at Swansea in Wales, a cable report of which, prepared by our special correspondents, will be found in another column of the present issue, seems to have been fully up to the average in interest and in the importance of the subjects discussed in the several sections. A sign of the times, and one indicating the increasing dignity of the profession of medicine in Great Britain, was the election of the Prince of Wales to honorary membership in the association. A century ago, or even fifty years ago, the physician was a nonentity, ranking below the parson and but little above the butler in the social scale, and even yet, in military life especially, his worth is far from being recognized at its full value. A great lift was given to the profession socially when the present King, then Prince of Wales, accepted membership in the British Medical Association as well as in the Royal College of Surgeons, and this upward progress is now assured by the fact that the son is following in his father's footsteps as a friend of the doctors. In a country such as England, where the lines of class distinction are still quite sharply drawn, the raising of the medical practitioner in the social scale means much more than a mere recognition of him by what is called "society"; it means that his influence as an adviser on matters of hygiene and public health will thereby be widened, and that his views on such subjects will receive increasingly more respectful attention in the future than they have in the past.

In these times when everything is tending to increase the friendly relations existing between the two great nations using a common English speech, the doings of our confrères in Great Britain have an added interest for American physicians. It was this that prompted the MEDICAL RECORD to present its readers with the cabled abstract of the meeting here furnished, which will, of course, be supplemented with the usual full report by mail of the principal sections. It would have been an added satisfaction could we have published in this issue an account of the entire meeting, but as the association is still in session at the time of this writing, a complete report is manifestly impossible. We give our readers, however, the latest news up to the moment of going to press, and in so doing maintain the established policy of the MEDICAL RECORD always to present a prompt and accurate account of medical happenings in all parts of the world.

## KORSAKOFF'S DISEASE—POLYNEURITIC PSYCHOSIS.

AMONG the many forms of mental disorder a few are recognizable by the non-specialist, among them the form described first by Korsakoff some fifteen years ago as accompanying multiple neuritis of alcoholic origin. Osler refers to this disorder when he says that many patients with alcoholic polyneuritis lose their grasp upon time and place, narrate events long past as of recent occurrence, and tell of imaginary happenings. The last number of the *Journal of Mental Pathology* contains a critical study of Korsakoff's disease by Drs. Soukhanoff and Boutenko, on the basis of a critical review of the whole literature, and of cases personally observed. The following is a fairly typical case: A wigmaker, of strongly alcoholic-neurotic family history, aged 43 years, married, had drunk steadily a medium quantity of alcohol from 16; from 24 he suffered from constipation; about 32 he had marked pains in the feet, relieved by salicylates; and from the age of 38 he suffered from dyspnœa, faintness, and morning vomiting. In February, 1902, he was attacked by some acute infection, with two weeks' fever (reaching 40°C.), cough, sneezing, and pains all over the body; and, the first three nights, restlessness, insomnia, and hallucinations of alcoholic coloring; the attack ending in recovery. On September 6 the patient stopped drinking. A week later he grieved over non-success in setting up a business of his own, and took little interest in his surroundings. On the 27th, going to dress a lady's hair, he forgot to take his hairdressing appliances with him. The lady's anger had a marked effect on him; he had sudden vertigo, vomiting, three hours' unconsciousness, and involuntary urination, followed by pains in the temples for two weeks, inability to walk without support, ending in progressive improvement to October 11, when he had an attack of unconsciousness with foaming at the mouth, and, twenty minutes later, another attack lasting three hours with superficial breathing, biting of the tongue, and involuntary defecation. Admitted to hospital November 2, he was drowsy, though he answered questions. He did not know he was in a hospital, and was delirious to a high degree, at times mistaking persons (physicians for his chums; at other times, however, recognizing them), though recognizing his near relations. The reflexes were impaired; temperature 38.2°C.; pulse 130. On the 25th the temperature was normal, and the patient less depressed; he complained of pains and a sense of fatigue in body and head, and was quite weak. The right pupil was somewhat the larger, and the right soft palate somewhat lower. The biceps tendon reflex was absent. Tremor of the hands was present on extension. The lower extremities were markedly wasted, and there was pain on pressure over the right crural and ischial nerves. The knee-jerks were absent, the gait uncertain, and the patient swayed on standing feet together and eyes closed. He complained of marked pain in the feet. On psychical examination the most marked trait was the memory defect; he could not remember what he had just been told, or where he had come from. He said he had been in the hospital three days, which was incorrect. He could not tell the part of

the city, the day of the week or month, or his own height. He could remember remote events well, *e.g.* approximately the date of his birth, and the town and department where he lived. He made mistakes as to the age of his children, and mistook those about him for old friends. He thought his memory good. When he realizes that he cannot give a correct answer, he tries to evade the question. He tells with an air of perfect sincerity imaginary stories about his doings of the previous day; of a hunting trip, and of shooting some rabbits, where he had been, of drinking feats in company with his chums, etc. The simplest addition was done with the greatest difficulty. His disposition was good. In the course of the disease the memory defect remained unchanged. He, however, continued to tell fantastic stories; of having gone fishing, that an immense fish sprang at his friend, began to beat him, and tore his wedding ring off his finger, etc. At first he could not remember the doctor's name —later with great difficulty he managed to retain the names of only two of those around him, and he applied the names to the wrong persons. Gradually he learned to remember the day, date, and year. Gradually he stopped telling imaginary stories, and his amnesia came to apply especially to events of his own life beginning with his first attack. Nutrition and strength increased, the knee-jerks reappeared and electric examination showed the absence of the reaction of degeneration. What now are the distinctive features? The combination with the signs of polyneuritis (impaired tendon reflexes, weakness of the extensors of the leg, tenderness on pressure over nerve trunks, changed electrical behavior of the nerves), of memory defect and a marked tendency to the fabricating of "pseudo-reminiscences;" also usually a serene contentment, often a little realization of the memory defect, frequently defective grasp as to surroundings (place, date, persons, etc.). In addition also, of course, tremor of hands and tongue. Altogether 192 cases are on record, 112 in women and 80 in men. The predominating cause is chronic alcoholism (in almost three-fourths). More especially is this true in regard to women. In them also local septic foci enter more into the etiology than in men. In men most cases occur between 40 and 50 years; in women between 36 and 40 years. There has been much discussion as to the necessity of a connection with the psychosis, of the polyneuritis. The author's collection shows that polyneuritis was present in all the recorded cases in women, and in all but ten of those in men. They find that in men psychic defects remain in half the cases. Death is frequent, tuberculosis being often the immediate cause. Of the women, 14 recovered, 6 were possibly hopeful, in 20 psychic defects remained, and 21 died. Eleven of the 14 recoveries were of alcoholic origin.

## THE EARLY HISTORY OF QUARANTINE.

Past Assistant-Surgeon J. M. Eager of the Marine Hospital Service contributes the Yellow Fever Institute, Bulletin No. 12, dealing with the above subject. Public sanitary measures, known as "quarantine," have been more extensively applied in America against yellow fever than against any other disease. "The history of quarantine," says the writer, "is closely interwoven with that of medicine in general and of shipping. We read of these practices being applied against leprosy in Biblical times, and Captain Cook, the English navigator, tells us that the savages of the South Sea Islands, who had not advanced beyond the stone age at the time of his visit to those islands, resorted to crude sanitary precautions in the case of arrivals from neighboring places."

The story of the beginnings of quarantine is associated particularly with the epidemiology of leprosy, pest, and syphilis. Cholera and yellow fever were later considerations. The first reported prevalence of yellow fever was at Bridgetown, Barbados, in 1647, the year before the great pest of Havana. At this time quarantine measures had been practised against other malignant contagious diseases, a maritime quarantine station having been in operation at Venice in 1403, nearly a century before the discovery of America. The first appearance of yellow fever in Europe occurred at Lisbon in 1723, but it was not until 1821, following an extensive epidemic in Spain, that quarantine was applied in Europe against yellow fever."

Land quarantines against leprosy were the first mentioned in literature. Precautions to be taken against this disease are formulated in the Old Testament, isolation being ordered for persons who were found to be afflicted with leprosy. The Crusaders brought back with them to Europe from the East numerous diseases, including leprosy, and the Eastern system of isolation was adopted. Leprosy, however, had been introduced into Europe many centuries earlier, although, during the crusades' epoch it became much more widespread than ever before. It was in connection with pest, and later with syphilis, that maritime and land quarantines were established in medieval times. The term pest in those days was far more comprehensive than at the present time, not only did it include bubonic plague, but different epidemic diseases, which were then placed in the same category. Hippocrates believed epidemics to be air-borne, while Galen held somewhat similar views. The first man to preach the doctrine of contagion by contact, was Jacopo della Torre, an Italian, who was born in the second half of the fourteenth century, and his theory was ably upheld by the writings of Allexandro Benedetti, Marsilio Ficino, and Gerolamo Fracastoro. Ficino was of the opinion that pest could be communicated from man to swine, and that cats and dogs might convey the disease. He advised that all drinking water should be boiled, or that it should be impregnated with iron rust, and that persons should dwell on hills or in mountainous regions. He gave many injunctions as to treatment and diet during times of pest, some of which are followed to this day.

Fracastoro, influenced by the prevalence of syphilis in Europe, wrote in 1546, the work, "De Contagionibus," in which he divides contagious diseases into three classes, namely, disease-catching by contact; disease carried by fomites; and disease conveyed by air.

Maritime quarantine originated in connection with the Levantine trade. The Venetians were, it is generally admitted, the first to make provision for maritime sanitation, and the first thoroughly

constituted maritime quarantine station of which there is historical record, was established in 1408 on the island of Santa Maria di Nazareth, at Venice, and in 1459 a public bureau of sanitation existed in Venice. In 1576, owing to the frequency of strange febrile diseases, the supreme magistrate of health of the Republic of Venice, suspecting pest, called a conference of great physicians, among others Girolamo Mercuriàle, Capodivacca, and Nicola Massa.

The maritime quarantine stations of the sixteenth century consisted of an anchorage, barracks for suspects and convalescents, and a place where purification could be applied. A vessel, suspected of being infected with pest, was, upon arrival, thoroughly disinfected, some of the clothing of its crew and passengers being burned, some washed, aired, and perfumed, for fifty days. The sick were sent to a lazaretto. It was not until the middle of the last century, following the investigations of Pasteur, Pollender, and Bavaine, that quarantine practice became established on its modern scientific basis. English quarantine procedure prior to 1800 did not differ much from that of the Mediterranean ports. From the beginning of the nineteenth century quarantine restrictions were, by changes in the law and their application, materially relaxed in Great Britain, and as a substitute for former practice it has not been the custom in modern times to detain any vessel unless there has been communicable disease aboard during the voyage, or such exists on arrival.

The international sanitary conferences at Paris in 1851 and 1852, in which participated the different European powers having interests in the Mediterranean, marked the close of the old régime of quarantine. Delegates were present from France, Austria, the two Sicilies, Spain, the Roman States, Greece, Portugal, and Turkey. England was not signatory. Regulations were adopted much less restrictive than former ones, it being admitted that the efficacy of many measures formerly practised was doubtful or negative, science having proclaimed that, for the most part, pestilential maladies are not contagious. A revolution in quarantine methods, on the European continent, followed this declaration, and resulted in the general adoption of practices based on the limited communicability of epidemic diseases.

The foregoing is a condensed account of Dr. Eager's extremely interesting description of the history of quarantine, chiefly of its early history. It will be noted that quarantine in America is not touched upon. It is to be hoped that at a future date Dr. Eager may turn his attention to this phase of the matter, and its bearing on yellow fever, and give his views as to the efficacy of quarantine.

### The Cause of Hay-fever.

Professor Dunbar of Hamburg claims that he has been able to isolate the toxic substance, which in predisposed individuals is capable of producing hay-fever. The results of his experiments are given in the July *Edinburgh Medical Journal*. By injecting the isolated toxin into animals, he has been enabled to obtain from them a serum which antagonizes the poison: (1) With rye pollen he touched the nostrils of six persons, three liable to hay-fever, and three immune. In the former marked nasal symptoms followed, while the latter were perfectly unaffected. (2) The pollen was applied to the eyes of the same persons, and in those who suffered from hay-fever, lacrymation, œdema of the lips and even chemosis followed. The three persons who were not subject to the hay-fever escaped all symptoms. (3) He placed two persons—one hay-fever patient and one immune—in a glass room, and made each blow into a small vessel containing rye pollen. The hay-fever subject was attacked by all the characteristic symptoms of the complaint in a somewhat aggravated form. The other person suffered no discomfort. (4) He applied pollen to the arms of a hay-fever patient and itching lasting for hours was produced. He did the same to an immune person and no effect resulted.

Professor Dunbar made several investigations into the composition of pollen, under what conditions it is active and when inert, and concluded that hay-fever poison is a soluble toxin. He also decided that the starch bodies of the pollen contain the toxin, and he further found that only the starch bodies of the graminaceæ are active in this way. He injected pollen toxin hypodermically into a medical man who suffered from hay-fever. The patient suffered in fifteen minutes from all the symptoms of hay-fever, which for the space of four hours became worse. The injection was made in the forearm, and in twenty minutes it began to swell, and in the evening the intumescence extended from elbow to hand. This took some days to pass off. Another doctor—immune from hay-fever—suffered no inconvenience save a slight swelling at seat of injection. Finally he injected rabbits with toxin, and after several weeks obtained a serum which he found could neutralize the toxin. He also thought it probable that rye antitoxin would neutralize the toxin of other grasses.

The outcome of the experiments made by Professor Dunbar have, to a great extent, been confirmed by Sir Felix Semon and Dr. M'Bride in Great Britain. With regard to the clinical uses of the antitoxin, however, the matter is still *sub judice*. Nevertheless it is a great advance to have isolated the toxin of this extremely troublesome affection, and there would seem reason for the belief of Professor Dunbar that he has discovered an antitoxin for one form at least of hay-fever. It is not improbable, however, even if the pollen theory is correct, that there are pollens and pollens and hay-fevers and hay-fevers, and that the special pollen which causes an attack of the disease in one person will not affect another who may yet be susceptible to the pollen of some other plant. If that is the case, it will e necessary to manufacture as many antitoxins as there are varieties of hay-fever inciting pollens, and then to decide upon the special form of hay-fever from which the patient is suffering before selecting the appropriate antitoxin.

### Etiology of Dengue.

In the Medical Record of February 8, 1902, Dr. Harris Graham, Professor of Pathology at the American College, Beyrout, Syria, published an article in which he set forth his views as to the etiology of dengue. The opinions there recorded had been brought about as the result of careful observations during severe epidemics of the affection and of practical experiments undertaken by Dr. Graham. Beyrout is at certain times of the year a hot-bed of dengue, and consequently the opportunities for studying the disease are peculiarly favorable. The series of experiments carried out by Dr. Graham included direct inoculation by means of infected mosquitos of healthy individuals, the results of these

investigations convinced him that certain forms of culex may convey—as do anopheles the malaria germ—the disease from one person to another. Dr. Graham, in the article referred to, said: "It may not be absolutely proven that this hæmatozoon is the cause of dengue, but its constant presence in the red blood-corpuscle during the fever, its resemblance to the parasite of the Texas cattle fever, its likeness in manner of growth and mode of propagation (by the mosquito) to the malaria parasite, all point in the same direction, and lead us to believe by analogy, if by no other way, that in this parasite we have the cause of dengue." Again dengue with malaria and yellow fever—both of which are spread by mosquitos—disappears with the cold weather, the insects being inactive at that time. The Egyptian correspondent of the *Lancet* of July 4 propounds the theory initiated by Dr. Graham that dengue is conveyed by mosquitos, which is the *raison d'être* of our dissertation. The medical men of the United States Army who are stationed in the Philippine Islands might give efficient aid in solving the problem of the etiology of dengue, as the disease is very prevalent there.

### Antivivisection in England.

The crusade against vivisection is being prosecuted with more than ordinary rancor by the small but noisy band of its opponents in Great Britain. This narrow-minded and prejudiced body of men refuse to acknowledge that any good has or can come from experiments on living animals, despite the facts proving its undoubted benefit to the cause of science, which are being continually brought to their notice. Sir Michael Foster, recently in the English House of Commons, delivered himself of some weighty words in defence of vivisection. The noted physiologist said in part: "Vivisection experiments were not carried on with the clear certainty that the result obtained would immediately suggest a cure for any particular evil belonging to mankind. The result was a contribution to the general knowledge of mankind and an enlargement of the power of mankind. The increase of medical power that occurred year by year was due to the increase of medical science. Medical science from the time of Galen to the present time had been based in part on vivisection. It was based on many things—on observation on men, on observation on dead men, on observation on dead animals, and on experiments on living animals. Those elements were all interwoven, so that we could not pick out any part of the advance of knowledge as belonging to this head or that; and if we withdraw experiments on living matter the whole would fall together as a confused heap. . . . The descriptions heard of experiments were not true descriptions. The great object of the physiologist for the sake of the results was that pain should be abolished altogether, and a very large amount of the progress in recent years was due to the fact that the operations could be carried on without pain. It was only in a few rare cases when pain was a part of the study that anæsthetics were not used." Paget, in his recent work, "Experiments on Living Animals," has given a clear description of the reason for such investigations, and of the manner in which they are conducted, showing that vivisection is carried on in the most humane way possible, and that the results gained thereby for the behoof of humanity at large, are far in excess of any pain which may have been caused to animals.

Antivivisectionists, like antivaccinationists, are cranks, some of whom mean well, but many of whom are inspired in their propaganda by the desire of self-advertisement. The pity is that they lead astray the ignorant, who, not properly understanding the question, borrow their views from those who speak and write the most, and thus distorted ideas as to vivisection are propagated, and a wide prejudice created against the practice.

## News of the Week.

**"Journal of the Royal Army Medical Corps"** is the name of a new periodical which has been established in London. It is to be published monthly by John Bale, Sons & Danielsson, under the editorship of Major R. H. Firth of the Royal Army Medical Corps. There are to be several departments as follows: (1) Original articles written by officers of the Royal Army Medical Corps and others; (2) bibliographical notes on articles of importance and interest to the military services; (3) reprints and translations from military, medical, and other journals; (4) official gazettes and official information generally bearing upon the Army Medical services. The first number is dated July, 1903, and contains the following original communications: "A Report upon Hospital Arrangements on Board Transports," by Capt. G. B. Stanistreet, R.A.M.C. "A Case of Neurectomy of the Sciatic Nerve," by Lieut. Walter C. Stevenson, R.A.M.C. "Some Rare Ocular Manifestations of Venereal Disease," by Major M. T. Yarr, R.A.M.C., and "Report on the Medical Relief Expeditions to Martinique and St. Vincent in Aid of the Sufferers from the Volcanic Eruptions of May, 1902," by Major J. Will, R.A.M.C.

**"Important, if True."**—The sea-serpent has not been heard from this summer, but we don't miss him. The newspapers of Sunday last contain a circumstantial account, telegraphed from Anderson, Ind., of the creation of living matter out of salt, by Dr. Charles W. Littlefield of Alexandria in the same State, a graduate of the Kansas City Homœopathic Medical College in 1896. The biogenic substances employed were: one ounce of common salt, six ounces of pure water, six ounces of 90 per cent. alcohol, all mixed in an ordinary glass dish, and two ounces of aqua ammoniæ distributed in five small plates and all covered with an airtight glass jar. "In ninety minutes salt crystals were impregnated with the hydrogen and volatile magnetism of the chemical solution and transformed into living forces that immediately sought nourishment through mediums that Dr. Littlefield called feeders, lacking a technical name." Indiana is so full of poets and best-selling novelists that creation, or the making of something out of nothing, comes easy there.

**Suit against a Hospital.**—Mr. John H. Calder has begun an action in the Supreme Court against the General Memorial Hospital in this city, to recover $100,000 damages for the death of his wife. Mrs. Calder died in February last in the hospital, where she had gone to be operated on, and the complainant alleges that her death was due to the carelessness and inexperience of the nurse who attended her. From the complaint it appears that the nurse was directed to rub Mrs. Calder with a mixture of alcohol and ether. Instead of using the electric light, it is alleged the nurse lighted a candle, and the stuff caught fire after it had been spread over the patient's body. The candle stood in a glass on the bed, and upset, setting fire to the bed clothes. Before the flames could be extinguished the patient had received mortal burns and died four days later.

**The Missouri Valley Medical Society.**—The annual meeting of this society will be held at Omaha on

September 17. A symposium on Skin Diseases will be a feature of the program. Those desiring to read papers should announce their intention, sending the title of the communication to the secretary, Dr. Charles Wood Fassett of St. Joseph, Mo., not later than August 10. The president of the society is Dr. J. M. Barstow of Council Bluffs, Ia.

**An Exposition of Child Life.**—Announcement is made of a unique international exposition which will be held in the imperial palace of Tauride, at St. Petersburg. The undertaking is called The Child's World, and will be under the patronage of Her Majesty, Dowager Empress Mary Fedorovna. Their will be assembled at "The Child's World" everything relating to the moral, physical, and intellectual education of childhood and youth. The exhibits have been divided into five sections, as follows: Section 1 on scientific teaching will show the aids in teaching children by means of manuals, books, maps, and pictures. Section 2, which is the one of special interest to medical men, will be devoted to that which pertains to the physical development of children. In this section will be considered the care of the new-born, hygiene before school age and of school children, nourishment, children's playgrounds, and the like. Section 3 is the industrial one, where there will be exhibits in nursery surroundings, furniture, lighting, heating, ventilation, beds and bedding, and children's clothing. In this section will be shown also the toys and games of children all over the world. Section 4 will be the art section, in which child life in pictures, by artists of all schools, will be shown in oil, water colors, pencil drawings, and all methods of reproductive art. Section 5 is the historic-ethnographical section, where there will be illustrations of historical events from the lives of child heroes, discoveries and inventions made by children, works and compositions by young artists and composers, and ethnological peculiarities in the lives of children of different nations.

**Report of the Autopsy on the Pope.**—The following were the findings of the autopsy made on the body of Leo XIII by Dr. Giuseppe Lapponi on the afternoon of July 21: After the injection of five liters of a special preserving fluid the abdomen was opened and the bladder and intestines were extracted. They were found to be perfectly healthy. The spleen and kidneys were also absolutely normal. In the latter the cortical substance was well preserved and of a pale pink color. After the thorax was opened it was found that the heart, the aorta, and the carotid arteries were healthy, except that in the arch of the aorta was found an atheromatous patch. Nothing unusual was found in the pericardium. The pleura on the left side was quite normal, but on the right side the pleural cavity was full of liquid of an orange yellow color above and bloody at the bottom, with a large clot of fibrin. More fibrin was on the free surface of the costal pleura, but this was easily detached, allowing a view of the serous surface. The upper part of the right lung was quite normal, but the lower part was somewhat hard and crepitated when compressed, and from the cut surface a whitish, frothy liquid oozed out. The inferior lobe had partly adhered to the wall of the thorax, and when this was cut a dirty, white, abundant liquid, without gas, oozed out, showing complete hepatization. The anatomical diagnosis made by all the doctors present at the autopsy was that of gray hepatization of the right inferior pulmonary lobe, with much pleuritic liquid of a serous fibrinous character, partly hemorrhagic, thus confirming the clinical diagnosis.

**Pensions for Health Officers.**—It is stated in the *Medical Press* that a recent number of the *Official Gazette* of Spain published the Royal decree announcing, over the signature of the Director-General of Health, the conferring of a pension on all medical health officers who may be incapacitated from work by any epidemic. And in case of death resulting from disease contracted in discharge of their duty their widows and orphans are to receive a pension.

**Bequest to the Newark Eye Infirmary.**—By the will of the late Eugene Vanderpool, a bequest for $10,000 is left to the Newark Charitable Eye and Ear Infirmary in memory of his wife, Eleanor B. Vanderpool, which the testator directs to be paid within twelve months after his death.

**Medical Examinations on a Jewish Holy Day.**—The New York State Board of Medical Examiners, in arranging for the examinations this year, set them for the date which is the Jewish Day of Atonement. The Union of Orthodox Jewish Congregations sent in a protest to the examiners and requested that the examination day be changed. In reply Secretary M. J. Lewi wrote that no alteration could be made this year because changing the long-advertised dates of the examination would be extremely unfair to many whose plans have been arranged in keeping with the schedule. He requested the society, however, to furnish the Regent's Office with the days and dates of coming Jewish holidays, so that future examination dates, not already scheduled, could be arranged so as not to conflict with the observance of those days.

**Mosquitos and Dengue.**—The Board of Health of Honolulu, acting upon the belief that dengue, which is now prevalent in the Hawaiian Islands, is spread through the agency of mosquitos, has instituted a crusade against these enemies of the human race. The results of their warfare will be watched with interest by some discouraged folk near New York.

**Obituary Notes.**—Dr. DONALD MCLEAN of Detroit, Mich., died at his home in that city on July 24, of gastroenteritis. He was born in Ontario in 1839 and was graduated from Edinburgh University in 1862. He practised medicine in Kingston, Ont., until 1870, excepting the years 1863-64, when he was a surgeon in the United States Army. In 1870 he became professor of surgery in the University of Michigan and held the chair until 1889. He was for several years chief surgeon of the Michigan Central and Grand Trunk railroads, and in 1894 was president of the American Medical Association.

Dr. JOHN EVANS WALKER of Columbus, Ga., died suddenly in that city on July 23, of cerebral apoplexy. He was a graduate of the New York University Medical School in 1886, and was for a time immigration medical inspector for the United States Government at Ellis Island, New York Harbor. Later he removed to Columbus, where he soon acquired an extensive practice.

Dr. LAWRENCE STEWART EDWARDS of Patchogue, L. I., died there on July 25 of cerebral apoplexy. He was born in Patchogue on July 4, 1855, and was graduated from the Bellevue Hospital Medical College in 1876.

Dr. MILO HOTCHKISS JONES, son of Dr. Leander Jones and assistant to his father as Health Officer of Greenwich, died there on July 27 of a fever contracted two weeks ago while attending to his duties. He was born in Kensington, Conn., twenty-eight years ago, and was graduated from the Yale University Medical Department in the class of 1896. He served for a term on the house staff of Bellevue Hospital in this city.

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

CAVENDISH LECTURE—DISEASE OF ASCENDING AORTA—HOWARD KELLY IN SCOTLAND—GYNECOLOGICAL SURGERY—SANITARY INSTITUTE—HOSPITAL BALL—ELECTION AT THE ROYAL COLLEGE OF SURGEONS—MR. BLOXAM—DUBLIN LOCK HOSPITAL—ALLINSON AGAIN.

LONDON, July 10, 1903.

THE Cavendish Lecture was delivered on the 24th ult. by Prof. Clifford Allbutt, and was, of course, in his usual picturesque style, which some affect to consider too ornate or popular for dry scientific discourses. He took as his subject Disease of the Ascending Aorta, and spoke at the outset of the strain to which it is subjected. "The endurance of the arch of the aorta under the incessant lashing of the blood for three-quarters of a century" he found remarkable; although in persons above fifty years of age there are usually signs of wear or injury, greater in those who have spent lives of muscular labor. The constant strain must enter more or less into the sum of its lesions and the seat of their greatest severity. Disease of the aorta has a certain independence of affections of the heart or even of the aortic valve.

Inflammation may attack the aorta in the course of infective diseases, but is not always dangerous; it is sometimes slight and transient, but should always be watched, for as it is more frequent in the exanthemata than was at one time supposed. It may determine a fatal issue or may disappear in a few weeks, even in smallpox cases. In rheumatism it is generally an extension from the heart, but not always.

Perforating aortitis is not so rare as some suppose; perhaps some aneurysms arise in this way. Suppuration is sometimes overlooked post mortem, as it does not break into the channel of the vessel. The pus lies in foci in the adventitia, and in the middle coat "it is a periarterial affair, and usually but a small and secondary item in some much more extensive pyæmia." But inner aortitis is not uncommon in septic diseases. In typhoid fever the transient form is common in the later weeks or during convalescence, but is likely to escape notice. The relation to influenza, diphtheria, pneumonia, malaria, and other diseases was considered, and a remark was made on the experimental side of the subject.

Passing from acute to chronic aortitis, Dr. Allbutt likened to passing from obscurity to certitude, but he had some interesting statements to make. He thinks disease of the ascending aorta as distinguished from diffuse atheroma gets too little attention; it may occur alone, or nearly alone, and though the symptoms may be equivocal it may compass the patient's death. It is more common in middle and even early life than is generally realized, and is for the most part insidious.

He would restrict the name atheroma to the decaying, the necrotic processes, and when repair predominates speak of aortitis. He urged that in this as in all chronic maladies tides of acute activity take place—exacerbations, vacillations, and notable changes. Thus angina may quickly appear when at worst a more gradual and less dreadful mode of decline had been expected.

It may be taken as agreed that the higher the blood pressure the greater the strain on the aorta. Perhaps in every case of cardiac hypertrophy some atheroma of the aorta occurs. If with advance in age resilience diminishes, normal, or even subnormal, pressures may become relatively excessive, one or another part of the vessel yield, and stress become unequal.

Though the lecturer did not propose to include aneurysm, he mentioned those which are too small for direct observation, which are apt to form about the root of the vessel, and are usually due to aortitis. In this area recesses are often found post mortem. Some too small to contain a clot, others narrow-mouthed and aneurysmal in the saccular sense, tending to rupture into the pericardium, or to compress the base of the heart. They are not to be diagnosed during life, unless, perhaps, by the Röntgen rays, though they sometimes give rise to angina, or to signs of aortic disease. Like other lesions of this part, they are apt to retard the pulse rate, a phenomenon not altogether dependent upon interference with the coronary circulation. Of gout as a causative influence, Dr. Allbutt remarked that urate of soda has never been detected in the aorta, and experimental injections of uric acid have no effect upon it; hence the hypothesis of a sitting up of the vasa vasis by crystals must share the fate of many another ingenious suggestion.

Our Scotch friends have had the pleasure of entertaining Dr. Howard Kelly, and at a combined meeting of the Glasgow and Edinburgh Obstetrical and Gynæcological Societies he opened a discussion on the indications for particular methods of extirpating diseased pelvic viscera. He put in a plea for more conservatism than sometimes appears in this field of surgery. In a woman under forty years he would make every effort consistent with a reasonable expectation of restored health to avoid the loss of such important structures; for, while the removal of diseased tissues which could not be regenerated is a boon, the sacrifice of a sound organ should be called by its proper name—a mutilation. Exsective surgery had in these cases, he might almost say, run riot. As regards the ovaries, he believed half the cases of their removal which he had seen were unjustifiable. If he found them adherent but otherwise healthy, he released the adhesions and did no more. He would rather run the risk of having to operate a second time than remove ovaries when in doubt of the necessity of doing so.

Dr. Kelly described his methods of operating in different cases, and in the discussion which followed it was generally acknowledged that his address marked a great advance in the several procedures.

The meeting of the Sanitary Institute is in full swing at Bradford. The most interesting section is, perhaps, that presided over by Dr. Spottiswoods Cameron of Leeds and devoted to the medical officers of health. According to him the 'Margarine Act is a complete failure, as the article is not usually exposed for sale. but stands behind a show-case or on a back shelf and so does not require the distinctive label. This is an illustration of the difficulties of contending with dishonest tradesmen by such kind of legislation. The use of deleterious preservatives in foods, especially in milk, was discussed. Dr. Moore of Huddensfield advocated the appointment of qualified assessors to assist the magistrates in dealing with scientific evidence. A resolution was adopted that whenever preservatives are used, their presence, nature, and maximum amount should be declared on the label.

Professor Oliver presided in the section of hygiene, the text of his address being the tension of modern life and its evil effects on the workers. He found it impossible to estimate the good accomplished by our factory legislation, which has saved thousands of lives, and averted thousands of accidents. Still there is on the other side, he said, the silent procession of men and women worsted in life's struggle, and for those whose health had been undermined by occupation diseases, or who had been rendered unfit by accident, he held that the plea of sanitarians should still be—"prevention is better than cure."

A great ball in aid of Charing Cross Hospital was held at the Albert Hall last night. It has been organizing for weeks among a very smart set, and the vast building is said to have been converted into a sort of fairy palace for the occasion. The arena set apart for dancing was festooned with roses upheld by standards of electric stars at intervals. Many of the guests were in fancy dress, and some of the dances were arranged to represent particular periods. The entertainment is pronounced to be one of the best of the season. I hope the benefit to the charity will be proportionate to the lavish, and perhaps extravagant, expenditure.

Mr. John Tweedy was elected President of the Royal College of Surgeons yesterday. Mr. Henry Morris and Sir A. Cooper were chosen vice-presidents.

Mr. J. Astley Bloxam is about retiring from the Senior Surgeoncy of the Charing Cross Hospital, with which he has been connected for thirty-three years. He has seen the hospital progress in size and influence through this important period of surgical progress, and will, naturally, retain a deep interest in the school where he has been a favorite teacher.

T. R. Allinson, who was struck off the Register, continues his practice as boldly as ever. He was before a coroner lately, in reference to a death, when he stated that his certificates are usually accepted by the registrars, and boasted that he did not care about medical authorities, as he was an authority himself and had as large a practice as any in the Kingdom—thereby calling on himself the coroner's rebuke, as that was not a place in which to advertise himself. The Registrar-General should see about the acceptance of his certificates.

The Dublin Lock Hospital seems likely to furnish the next example of mismanagement. I hear that three out of four staff nurses of many years' standing have resigned rather than put up with the ways of the matron. The board, instead of inquiring into the matter, asked the remaining nurses to resign also.

---

**Compulsory Vaccination in France.**—A law has recently been enacted in France requiring all parents to have their children vaccinated before they have completed their first year of life, and also compelling every one to be revaccinated between the ages of twenty-one and twenty-two years.

## OUR BERLIN LETTER.

(From our Special Correspondent.)

PLAGUE IN BERLIN—CONGRESS OF SURGERY—FINSEN'S METHOD IN LUPUS—CACHEXIA WITHOUT PATHOLOGICAL LESIONS—INSTITUTE FOR POST-GRADUATE COURSES—RESEARCHES ON CARCINOMA—DEATH OF DR. JUERGENS—MEDICAL MEMBERS OF THE REICHSTAG.

BERLIN, July 10, 1903.

THE Berlin medical world has been startled by a fatality which happened at Koch's Bacteriological Institute. A young doctor named Milan Sachs from Vienna, who was designated as professor of pathology at Agram, was working at the institute on plague and there infected himself. A guinea-pig was vaccinated with plague bacilli and showed the usual symptoms of that disease a few days later. Dr. Sachs took, through a Pravaz syringe, some pus from a bubo with which he inoculated an agar plate in order to study the mode of growth. By accident some air had penetrated into the syringe and the liquid instead of dropping on the agar plate spurted suddenly, and it is thought Dr. Sachs inhaled some of the material. Two days later he showed symptoms of plague and was taken to the hospital and isolated, but died the next day.

Very stringent measures were at once taken by the government to prevent the disease from spreading. All persons with whom the late Dr. Sachs had come into contact during the last few days were isolated and vaccinated with plague-serum from the Pasteur Institute and the whole furniture was burned. Thanks to these precautions there were no further cases of plague.

This case recalls a similar case which happened two years ago at Vienna to Dr. Müller, one of the members of the plague expedition to India. One of the servants of the Vienna laboratory infected himself and was treated by Dr. Müller. Eventually Dr. Müller was infected too and died of plague. Both these cases at Vienna and Berlin show the facility of infection and both remained local, owing to the strict precautions taken.

It will be remembered that the Vienna Government has forbidden experimental work with plague bacilli, but the Berlin Government still maintains a laboratory at Koch's Institute for Infectious Diseases for the purpose of having always some serum at its disposal should plague be brought accidentally to Germany.

In the beginning of June the annual congress of the German Surgical Society took place in Berlin. The meetings were at the Langenbeck House, Professor Kuster from Marburg being president. Dr. Perthes of Leipzic read a paper on the influence of *x*-rays on carcinoma. Several patients with rodent ulcer of the skin and carcinoma of the mamma had been cured by prolonged application of *x*-rays. Dr. Lassar of Berlin, as well as Dr. Petersen of Heidelberg, had seen similar good results with *x*-ray treatment of carcinomata of the skin. Drs. Sonnenburg and Federmann of the Berlin Moabit Hospital read a paper on the great importance of counting the leucocytes in cases of appendicitis. The method has been employed for some time at the Moabit Hospital and good results have been seen. An increase beyond 15,000 indicates an abscess for which surgical treatment is indicated. A discussion arose on the indications for operation in the early stages of appendicitis. Riedel insisted that it ought to be operated as soon as possible—as soon as the diagnosis of appendicitis is made. Dr. Petersen remarked that the carcinomata of the stomach differ from rectal carcinoma, the latter grows more into the deeper tissues, whereas the first is more inclined to increase superficially. He thought that a greater number of cells disappear in the glands than is usually believed. Of thirty patients who were operated upon twelve died during the operation; of the remaining eighteen seven were still alive. As the glands were not all extirpated, and surely some cells remained in the glands, Petersen believed that his view was correct that many carcinoma cells disappear in the glands.

At the Berliner Medicinische Gesellschaft Grawitz read a paper on cachexia without pathological lesions. Grawitz was consulted by a gentleman who suffered only from anæmia and want of appetite. No hydrochloric acid could be obtained from his stomach. Though the patient was well treated, he subsequently died. The post-mortem examination showed all the organs intact, even the glands of the stomach were not affected. Pernicious anæmia was also excluded, as the bone marrow was normal. Grawitz believed that some chronic intoxication resulting from the absence of hydrochloric acid was probably the cause of death. He had noticed that with patients suffering from tuberculosis there was often found a lack of hydrochloric acid, and good results had followed the administration of this acid. Senator thought that Grawitz's theory was disproved by the fact that persons could live without a stomach, and that in cases of chronic nephritis, tuberculosis, and neurasthenia patients might live for years, no hydrochloric acid being obtainable, and yet no symptoms of stomach trouble being shown.

At the [Gesellschaft] der Charité-Aerzte Dr. Lesser reported on the results with Finsen's treatment of lupus. The bacilli are killed by the constant light in the tissues. The best results were obtained in cases that had not yet been treated, but in cases in which scars remained with infiltration of the lower parts of the tissues very bad results were obtained. The mucous membranes of the nose and palate were also not accessible to treatment. The treatment took a long time and was expensive, therefore the speaker thought it advisable to build special sanatoria for Finsen's treatment.

The donation of the late Empress Frederick for medical researches and post-graduate work amounts now, with othergifts, to 1,200,000 marks, and steps have been taken to erect a large institute for these purposes.

Dr. Juergens, professor at the Berlin Pathological Institute, died recently, aged sixty years. He was for thirty years assistant of the late Professor Virchow. Juergens is known through a new reaction on the amyloid degeneration of the cells. He also published a work on protozoa and malignant tumors.

Dr. Plehn has been appointed head physician to the Urban Hospital instead of Dr. Stadelmann, who has become head physician at the Friedrichshain Hospital. Dr. Plehn was a government medical officer in Africa and has worked on malaria. Dr. Wilhelm Braun, first assistant surgeon at the Augusta Hospital, has been appointed to the Friedrichshain Hospital.

At the recent elections six doctors were returned as members of the Reichstag. These are Dr. Mugdan of Berlin (Radical), Dr. Krzyminski of Inowrazlaw (Pole), Medical Privy Councillor Dr. Hoeffel of Buchsweiler (Imperialist), Dr. Leonhart of Kiel (Radical), Sanitary Councillor Dr. Ruegenberg of Bonn (Center), and Dr. Becker of Hessen (National Liberal). Dr. Mugdan's election is heartily welcomed, as he has many times proved to be of great help in social medical matters; and owing to the fact that the whole medical profession is suffering in Germany from the club-system (Kassenvereine), much is hoped from Dr. Mugdan's services as a member of the German Reichstag.

---

## OUR LETTER FROM THE PHILIPPINES.

(From our Special Correspondent.)

RECRUDESCENCE OF THE PLAGUE IN THE ORIENT—SPREAD OF THE DISEASE BY OTHER ANIMALS THAN RATS—VALUE OF PREVENTIVE INOCULATION—INEFFICACY OF MEDICAL TREATMENT—SLIGHT DANGER OF SPREAD IN THE UNITED STATES—THE RESULTS OF PRACTICAL SANITATION.

MANILA, June 20, 1903.

PLAGUE is again existing in Hongkong in seriously epidemic form. During the first five and one half months of the present year 1184 cases have occurred, with a total mortality of over 90 per cent., and during the latter part of May and early June, the deaths from this disease were occurring at the rate of over twenty a day. At the beginning of the epidemic the disease was confined entirely to the Chinese. Later the better quarters of the city were invaded, and Japanese, Eurasians, and East Indians were attacked. Now the white population is suffering, and last week twelve cases occurred among whites, while four cases appeared among the white crew of a ship in the harbor. Beginning with the bubonic type, which seems to be only slightly transmissible to whites, the character of the disease has changed to the septicæmic, and later to the pneumonic type, which latter seems to be the form in which plague nearly always occurs in whites. Of course in this last type the disease is extremely communicable, and is also more certainly fatal to the Chinese, and more difficult to diagnose. Whites have a proportionately high resisting power against plague, and of the twenty-five cases which have occurred among Europeans in this outbreak, but four have been fatal. Since 1898 there have not been two consecutive months in which plague has not occurred in Hongkong, although there have been periods when the number of cases was not large. June and July are the worst months, and this year June is sustaining its reputation in this respect. Conditions have been so bad that the Catholic church has held a number of services to pray for the abatement of the epidemic.

Plague has lately been made the subject of extended investigation by Dr. W. J. Simpson, an English expert, who was sent to Hongkong for the purpose. His conclusions with reference to the disease in that city are not very encouraging, as he believes that so long as plague exists in southern China it is almost impossible to keep it out of Hongkong, because of its wide trade relations, proximity to the infected Chinese cities, and readiness of communication with them. Dr. Simpson believes,

however, that by increasing the medical and sanitary staffs in Hongkong, and inaugurating a closer system of inspection that the disease can be held within reasonable limits.

Dr. Simpson states that his investigations show that in addition to the spread of plague infection by infected rats, houses and clothing, it is possible for pigs, calves, carabao, sheep, geese, turkeys, cats, pigeons, dogs, and mice to become carriers of the infection. His researches and conclusions incline the medical men of Hongkong to modify the belief heretofore held by them that the disease is mainly acquired by infective inoculation.

While the authorities in Hongkong are making every effort to place the city in good sanitary condition, and exterminate the rats, they have not resorted to the wholesale preventive inoculation against plague which seems, far more than anything else, to have cut down the disease in Manila. The Chinese in Hongkong are opposed to all sanitary measures, but particularly object to inoculation, and the authorities seem to have hesitated to excite still further their opposition. Any person who desired to be inoculated could have the operation performed, but this was not compulsory, and it seems to be largely due to this fact that the disease has made such headway. Experience in Manila goes to show that inoculation with antiseptic prophylactic virus, repeated in ten days, is as certain a preventive of plague as vaccination is of smallpox. It has been made compulsory with respect to all the 60,000 Chinese in Manila, and during the last two months a large proportion of these have been inoculated. The epidemics in Hongkong and Manila started at the same time, and the number of cases in both cities progressively increased at the same rate up to the time systematic inoculation was instituted here. The Chinese in the worst infected districts were inoculated first, and the decrease in the number of cases was not only great, but was noticeable within a few days. Thus in Manila there were two cases in January, seventeen in February, and forty-two in March. Inoculation was begun about April 20, and during April there were but fifty-two cases, while in Hongkong the cases more than doubled. In Manila the cases for May fell to twenty-five, while in Hongkong the number of cases doubled each week, and the total for the month was nearly 500 cases. In June the number of cases in Manila up to the 19th of the month was but nine, while the latest Hongkong report shows 136 cases in one week. In Hongkong a large number of contacts acquire the disease; here the contacts are immediately inoculated with Shiga's curative serum, and only six contacts have developed plague—and of these three cases developed so soon after the original case as to render it almost certain that they became infected at about the same time as the original case. Further, plague has repeatedly occurred here in large Chinese lodging-houses, in the person of the only uninoculated inmate, while the others entirely escaped, and it has never occurred in an individual who has received the proper double inoculation. From experience, there would seem to be no question but that while general sanitation and rat-catching is of importance, by far the most efficient agent in combating the disease is found in systematic and thorough inoculation of the class of persons who are most liable to contract the infection. It is not to much to say that there is every reason for belief that if systematic inoculation of the Chinese population in Manila had not been enforced, several hundred cases would have occurred during the past month, and the disease would not be confined, as it is, to certain districts in the poorer quarters of the city, and have been prevented from spreading to other cities and to the country districts, as it has done in India, China, and other points on the Asian mainland. The conditions here are unquestionably favorable to its existence and spread, and that the latter has not occurred, and the disease appears to be rapidly tending toward disappearance is equally certain to be the result of the energetic measures taken. Even the Chinese themselves appreciate the value of the preventive inoculation, and the general opposition to this measure which existed last year has nearly all died away. Fortunately, the reaction which follows inoculation is but slight, and is productive of little bodily discomfort, and so far not a single untoward result has accompanied the operations carried out in such wholesale style. At first the fact that only Chinese were inoculated raised the idea of race discrimination, but this quickly disappeared when it became understood that the Chinese were alone inoculated simply because they were many times more liable to the disease than Filipinos or than whites, as shown by the statistics of previous outbreaks here, in Hongkong, and elsewhere. It is fortunate that it has not been necessary to inoculate others than the Chinese, who are very tractable and submissive to proper authority, for the Filipinos would unquestionably have opposed the measure if carried out on themselves, and might have seriously impeded the work, or caused the withdrawal of the regulations requiring such inoculation. It is doubtful if any important part of the Filipino physicians would have favored such inoculations, as few have any knowledge of, or belief in, modern measures of serum therapy or the creation of artificial immunity. As long as only the Chinese have been affected by the order requiring inoculation, the Filipinos have not interfered, as there is no love lost between the two races.

In addition to the work of inoculation, the destruction of plague houses and the destruction of rats, on ship and shore, is being vigorously carried out. About seventy-five official rat-catchers are employed, and these turn in at the sanitary stations between eleven and twelve thousand rats every month. The general keeping of cats is encouraged, for the Philippine feline, though by no means as large and powerful as the American cat, can do much toward the work of rodent destruction. It has also been found that the free use of chloride of lime, in drains and basements, is of much value in keeping rats away from houses, as they greatly dislike the odor of chlorine. This fact is of importance in preventing the migration of rats from plague houses to other habitations in the vicinity. Unfortunately, however, the odor of chlorine appears to be equally as distasteful to the Chinese and Filipinos as to the rats, and for this reason chloride of lime is not as freely used as is desirable.

All in all, the work against plague there appears to have brought about more than satisfactory results, considering the widespread infection of plague through the city, and the virulent type of the disease. The outbreak appears to be practically at an end, and measures will be taken to prevent and forestall any outbreak after the rainy season is over. So far there have been 150 cases in the present outbreak, of which but thirteen have recovered. No medical treatment appears to have been of any particular value. The patients die quickly, often in a few hours, and many are dead when found. It might be that intravenous inoculation of plague curative serum would be of value if given in the early stages of the disease, but there is little opportunity to do this, and the value of such treatment cannot be properly tested upon those who are already moribund. Of the value of the preventive inoculation there can be, however, no question. These facts seem to be confirmed by the present outbreak in India, where already more than 130,000 people have been destroyed by plague in the present year. There, however, the disease has ceased to be a city disease, and has widely spread over the country districts, the impoverished and poorly nourished natives seeming to have little powers of resistance against the infection. Caste, prejudice, and religious superstition have also largely interfered with the sanitary measures of the English authorities. To show how badly the Indian cities are affected it may be mentioned that the health report for Calcutta, of 1902, gives a total mortality of 38.4 per thousand, largely due to plague, and the number of plague cases during the year amounted to 7,883 in a total population of 808,969.

As plague is such a serious and ever-present problem in the Orient, the question naturally presents itself to the American sanitarian as to what hold the disease could obtain in the United States. Plague, perhaps more than any other infection, is essentially a filth disease, and appears to be able to flourish only under such conditions of insanitation as can exist only in the Chinese slums of San Francisco and the poorer quarters of a few of the larger cities. A well-fed white population living under the usual American sanitary conditions would seem to have little to fear from it, and should the infection be introduced among such a population, there should be little difficulty in stamping it out, provided the disease was recognized, the issue squarely met, and proper sanitary measures taken. All through the East the foreign quarters and concessions remain almost unscathed, while the natives of the surrounding native quarters may be dying by thousands. The white man who gets plague is the very rare exception, which simply illustrates the sweeping nature of the general rule. The disease has twice been stamped out in Australia after epidemics of no great severity, and throughout the Orient generally, has come to be regarded as one of the ills that white flesh is not heir to. With increasing trade relations and better communication with plague-infected ports, it can hardly be expected that plague will not, from time to time, gain entrance to the United States, but all experience here would go to show that the disease could become epidemic under such conditions only through the incompetence of the health officials. An intelligent and cleanly white population living among modern sanitary surroundings will scarcely fall victims to this Asiatic scourge, bred in ignorance, squalor and famine, and manifesting such selective performance for the dark-skinned races. It

may cost much in the way of money and labor to stamp it out, but that this can be done by intelligently directed sanitary [illegible] has been repeatedly demonstrated in Australia, Honolulu, Japan, [illegible] elsewhere, and would seem to be on the point of being accomplished under the highly disadvantageous conditions existing in the Philippines.

As with smallpox and typhus fever, and more recently with respect to malarial and yellow fevers, both plague and cholera may be prevented or controlled by ordinary cleanliness, sanitary surroundings, and a little attention to a few simple sanitary precautions. Pestilence loses much of its dreadful aspect in the light of modern scientific investigation, and ceases its slaughter when it is boldly attacked in a comprehensive way along its points of least resistance. One cannot but be confident of the ability of American medical men to rise equal to any sanitary situation, after seeing what they have accompilshed in Cuba, Porto Rico, and the Philippines, in less than half a decade, in the face of what had previously been regarded as insurmountable sanitary obstacles. Plague spots have disappeared, pestilence centers have vanished, and it has suddenly been discovered that places heretofore regarded as practically uninhabitable by white Americans have been rendered as healthful and salubrious as many parts of the home country. Not the least of the far-reaching results of the Spanish-American war has been the awakening of the public mind to matters of sanitation and a far better appreciation of their importance. It having been demonstrated what could be accomplished by proper sanitary measures, there will be much less opposition in the future to such measures, both at home and abroad. Even here the people are beginning to awaken to this truth and to appreciate what is being done in their behalf. They are much more willing to submit to sanitary regulations than they were a year ago. Nearly all of them have seen relatives or friends die of plague or cholera for refusing to follow the instructions of the sanitary authorities, and they have not failed to mark the small mortality among the white foreigners from these diseases at a time when the ignorant, heedless, and obstinate of their own race were perishing on all sides. In spite of racial and political dislike, the wiser heads among them are beginning to appreciate that the sanitary regulations of the Americanos, unduly severe though they may seem, are, nevertheless, accomplishing such results as were never obtained or approached during Spanish sovereignty.

## THE ADVERTISING OF OPERATIONS IN THE DAILY PRESS.

To the Editor of the Medical Record:

Sir: In your issue of July 11, I read with interest the letter of Dr. X. B. Haynie, and thereby am prompted to make a few remarks.

As long as the sun rises, so long will there be ample fruit for such a communication. First: Given a patient of prominence suffering from some grave affection, and attended by a physician or surgeon of equal prominence: Result, a daily or hourly bulletin giving with the report of the progress of the disease, the physician's name and perhaps, if he be "big" enough, his address.

Second: Given the same patient, same disease, attended by a physician of equal skill, but who may not have a newspaper reputation: Result, "Attending physician says so and so."

No physician need be exploited in the daily press, if he does not seek it. In the first case, the medical attendant receives no harm, for no one would dare think that he would voluntarily suffer his opinion to appear in the public press, and he is not averse to the pecuniary gain accruing therefrom, especially when without blemish to his ethical reputation. In the second instance, if the physician happened to be a young man, he knows very well that should he be "written up," he might receive a communication from his medical society.

The question seems to be narrowed down to this: The "higher up" one gets the more he may with impunity (so far as medical ethics are concerned) advertise. That fact is taken advantage of by some.

The medical profession is to-day crowded and is getting to be conducted upon a commercial basis, particularly as to the matter of fees. Many (not all by any means) of our friends who are shouting loudest about the strict observance of medical ethics are the very ones who will cut fees to the bottom notch, simply to get the work away from somebody else. This may seem a strong statement, but it was instanced only the other day, in a case upon which a friend of mine was about to operate for an ordinary fee. The operation was subsequently done by a man of large reputation, who would blush at the thought of transgressing the code of medical ethics, for a fee that would scarcely repay him for time and assistance, simply to "get the case." Could a stop be put to this practice, medicine would assume more of the air of a true profession, instead of a "bargain-counter affair." The lamentable part of the thing is the fact that this fee-cutting process is not limited to the man who really needs the financial remuneration, for in the instance just mentioned the gentleman was financially independent of medicine.

All hail with joy the day when we can eliminate the above class of practitioner together with his sidepartner, the "general specialist," the man to whom you refer your case, only to later learn that he has prescribed for the whole family.

H. W. Lincoln, M.D.
113 Hancock Street, Brooklyn.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, July 23, 1903.*

**Studies on the Action of Alcohol in Disease, Especially upon the Circulation.**—Richard C. Cabot summarizes his paper as follows: (1) In 41 patients, mostly cases of typhoid fever, 1,105 measurements of the blood-pressure were made before, during, and after the administration of alcohol in therapeutic doses. Neither the maximum nor the minimum blood-pressure showed any variations that could reasonably be referred to the action of the alcohol. So far as was determined by the methods and in the cases used in this research, the action of alcohol upon the circulation was *nil*. (2) The same neutrality and apparent inertness of therapeutic doses of alcohol in relation to the temperature, pulse-rate, respiration rate, appetite, sleep, delirium, and secretions (renal and cutaneous) of 309 patients suffering from a great variety of diseases was the total impression derived from 2,160 observations in these cases. (3) These observations are not interpreted as proving that alcohol is useless or useful in disease. As a narcotic and vasodilator it may have an important place in therapeutics. (4) More important probably than any of the questions investigated so far is the problem of the effect of alcohol upon the power of the sick man's blood to protect him against infection and other harmful influences. The studies of Abbott and of Mircoli have begun to clear a path in this direction, and we have a certain amount of evidence relative to a similar problem in the lower animals. But as the results of studies regarding the action of alcohol upon animals or upon healthy men cannot be used as evidence of its action in sick men, there is a good field for experimental work in this direction along the lines of Ehrlich's newer methods.

*Journal of the American Medical Association, July 25, 1903.*

**Limitations of Non-surgical Treatment in Acute Intestinal Obstruction.**—The paper by J. R. Eastman is a forceful yet temperate and logical plea for the abandonment of the old so-called expectant and "conservative" methods of treatment, provided their employment does not afford immediate relief. In general, urgency is not so great in obstruction of the large as of the small bowel, and in the former, sedatives, stupes, taxis, and injections may be properly employed for a longer time than in the latter. But if a fair trial fails to afford relief, temporizing is suicidal. There is only one indication, viz., immediate abdominal incision.

**Traumatic Pneumonia.**—By this title W. T. English refers to pneumonia set up by chest contusions in which there are no external signs of violence. An element of fright often enters in as a factor because it is associated with 90 per cent. of chest injuries. In more than half of these fright prompts a gulp of air, closure of the glottis, rigidity of the diaphragm and other muscles of respiration, and a fixidity of the thorax. There is also an attempt to free the arms, as in the attitude of self-defence. The chest is never guarded in this pose, instinctively responsive to the primal law of nature—self-preservation. The frightened human "holds his breath," and a stroke or fall on the chest is often received in the position of pulmonary disadvantage. To this condition of the chest is often added an advantageous angle for the force, because of the unfortunate position assumed by the individual. As a result of injury we may have, first, punctate hemorrhages from a capillary rupture, the parenchyma remaining intact; second, small tissue ruptures in alveoli, bronchioles and peribronchial vessels, and, third, actual tears of the lungs, bronchi, or vessels. Several illustrative clinical histories are given. A diagnosis is generally possible by the end of forty-eight hours after the injury. The sputum contains the diplococcus. Treatment must meet the indications of each special case.

*Medical News, July 25, 1903.*

**Pathology and Treatment of Alcoholic Toxæmia.**—Thomas D. Crothers states that it may now be taken as demonstrated that the various affections of the body and mind which are produced directly or indirectly by alcoholism are due to toxæmia. Alcohol acts first on the blood vessels. The vasomotor nerves surrounding them become paralyzed. They alternately dilate and contract, breaking up the uniform flow of the blood and diminishing the nutrition of the artery. Mechanical obstruction follows, with increased labor of the heart, also increased tension and feebleness. The heart hypertrophies and the liver becomes cirrhotic. Secondly, alcohol acts on the blood, reducing the number of red corpuscles which carry the oxygen. The number of white corpuscles is increased. Thirdly, alcohol acts on the nervous tissue, producing neuritis. The alcohol should be stopped entirely and at once. The bowels should be opened by salines and baths, and other means used to stimulate the pores of the skin. Narcotics are not given till the toxins have been expelled, nor is food given until the acute stage has been passed. The after-treatment should continue, with bitter tonics, of which cinchona is the best. Arsenic is valuable. Strong infusions of quassia will be found effective for the alcoholic craze.

*New York Medical Journal, July 25, 1903.*

**The Fever of Dentition.**—E. R. Corson refers to his two previously reported cases in which lancing of the gums in teething children was immediately followed by convulsions. He regards the fever of dentition as due principally to abnormal conditions in the upper bowel. Hence, in the febrile conditions attending dentition, it follows that interference with the gums is of secondary importance and, indeed, may be positively harmful. The proper remedies are calomel and castor oil. Corson places much value in the use of chlorate of potash in the mouth, the way for its local action being prepared by the preliminary employment of hydrogen peroxide.

**Removal of the Internal Jugular Vein and Carotid Arteries in Order to Remove a Tumor in the Left Side of the Neck.**—The patient of N. McPhatter was a woman of thirty-one years with a tumor (nature not stated) on the left side of the neck which, as the operation revealed, surrounded the carotid arteries, internal jugular vein, and pneumogastric nerve, apparently penetrating their walls. The author describes the general anatomy of the vessels and nerves of this region and then details the various steps of the operation. In spite of the dangerous region to which the operation was confined and the radical nature of the latter, the patient made an uneventful recovery, and in two weeks was well. A colored plate accompanies the paper and well illustrates the anatomical features of the case.

**The Irritability of the Facial Muscles: A Study of Its Physiological Causes and Clinical Significance.**—C. L. Dana states that his observations have been made by tapping the motor and sensory nerves, the muscles and tendons with a rubber hammer, by irritating the skin with a pinpoint and with applications of intense cold or heat. The tests have been made upon seventy-five persons, who were either healthy or had no nervous disease, 30 cases of paresis, 10 of tabes, 6 of nervous syphilis, 6 of paralysis agitans, 3 of Basedow's disease, 3 of paralysis of the seventh nerve, 2 of total paralysis of the fifth nerve, and many cases of alcoholism, hemiplegia, melancholia, and other forms of insanity. The various points brought out in the paper are summarized as follows: (1) A list of normal facial responses. (2) A list of responses found in pathological conditions. (3) A demonstration that most of these responses are direct or indirect muscular reactions, not myotatic, and not reflex. (4) That the only normal reflexes of the face are the supraorbital and frontoorbital. (5) The description of a new reflex rarely found in normal faces, the nasomental. (6) The occasional presence of a frontal skin reflex. (7) Some clinical observations as to the significance of the abnormal responses. Concerning the nasomental reflex, Dana states that it is uniformly seen in paresis, and is rarely, if ever, found in healthy adults, though it is found in cases of cerebral syphilis in which no paresis can be determined. The test is made by striking the side of the nose near the exit of the nasal nerve, the response being a contraction of the levator menti-muscle.

**Œdema of the Glottis.**—The literature of this subject is somewhat extensively reviewed by J. C. Gittings and J. H. Jopson, who report one case following scarlatina in a child of five years. Intubation and moist inhalations gradually gave relief and recovery followed. The general conclusions presented by the authors are as follows: (1) Simple œdema of the larynx usually occurs in cachectic diseases, especially of the heart and kidneys. In these there may be no apparent exciting cause, and the inflammatory symptoms are conspicuous by their absence. (2) Inflammatory œdema of the larynx results from contiguity to other inflamed structures; as a local complication of the acute infections of erysipelas, variola, measles, scarlatina, influenza, etc.; or as a result of severe grades of inflammation in simple acute laryngitis. Bacteriological investigation will probably find that a streptococcus is the most frequent exciting cause. (3) Traumatism to the laryngeal structures may result in œdema, depending on the degree of "insult" to the tissues or to a possible predisposition. (4) Among rare causes of œdema of the larynx are angioneurotic disorders and the blood dyscrasiæ, such as scurvy, purpura, etc. (5) The diagnosis rests on the evidence of palpation and, if possible, visual examination, as well as on the signs of laryngeal obstruction. Membranous laryngitis cannot always be at once excluded. (6) Prognosis is unfavorable in all cases occurring in the course of chronic cachectic diseases and in severe types of the acute infectious diseases. In no case can it be other than guardedly favorable. (7) Treatment by intubation rarely affords relief unless the obstruction is infraglottic. Tracheotomy is absolutely demanded in extreme cases. The continuous inhalation of medicated steam is always to be employed; scarification and external depletion by leeches may be tried; cold and heat should be used externally and internally—cold as a prophylactic and heat as a stimulant and absorbent.

*American Medicine, July 25, 1903.*

**Atropine in Cholera Infantum.**—Wm. F. Waugh declares that as a stimulant in collapse atropine has no equal. The dose for a child in the worst stage of cholera infantum, is a hypodermic of about $\frac{1}{100}$ gr., and upward, for children bear larger doses of this agent proportionally to their age than adults. First the blood comes back to the brain, the face flushes, the pin-point pupils relax, the vomiting and purging subside, and the pulse can once more be felt. Morphine should not be given. The patient may be kept slightly under the influence of atropine continuously, while the alimentary canal is being flushed and disinfected, and the cycle of the attack is completed. The application of ice or of any rubefacient to the neck over the pneumogastric aids materially in sedating this irritable region.

**Some Practical Considerations on the Tumefactions of the Climacteric Breast.**—Theodore A. McGraw believes that no breast ought to be adjudged cancerous without the most thorough examination by all possible methods, but when the surgeon, using his best judgment after full investigation, has come to the conclusion that he has to deal with a tumor of dangerous tendencies he should then operate on it so thoroughly as to destroy, if possible, every secondary growth, whether in fascia or muscle, skin or gland. He should assume that the skin above it, the fascia and muscle below, and all of the neighboring lymphatic vessels and glands are already infected, and should make the operation wide enough and deep enough to take in all of the suspected territory. In this manner success has been attained in at least a very large minority, which earlier surgeons have fallen short of. The writer has now many patients who are living without recurrences after three, five, and ten years. Above all, the patient should be kept out of the hands of the charlatans.

**The Pathology of Latent Malarial Infection as Observed at Autopsy.**—Charles F. Craig speaks, first, of the pathology of latent tertian infections. The lesions found were confined entirely to the spleen and liver, the most marked being in the spleen. This organ was considerably enlarged and dark bluish-gray in color externally. On section, the color was a dark brownish-red. There was intense congestion of the splenic sinuses with pigmentation. The pulp cells were greatly increased in number, many were pigmented and distorted. The sinuses and capillaries showed many parasite-infected red cells and pigmented leucocytes. The liver was but slightly involved. In the estivoautumnal infections, the pathology differed but slightly from that of the tertian infections, and chiefly in the character of the parasites present. The younger forms were similar to those found in the peripheral blood; the older ones were round or ring-like, and contained more or less pigment, in the form of very fine reddish-brown granules, this pigment being very slightly motile. Each segment appeared to present the ring form which is usually found in the red cell at the earliest stage of infection. No crescents could be found in the splenic sections. The writer concludes by saying that the malarial parasites may be present in the human body, may undergo their normal life cycle, and are practically localized in the spleen.

*The Lancet, July* 18, 1903.

**The Incidence and Mortality of Croupous Pneumonia in Infancy.**—C. Riviere concludes: (1) that croupous pneumonia occurs in infants below the age of two years as frequently as, and probably more frequently than, in older children; (2) that in infants a diagnosis between croupous pneumonia and bronchopneumonia is often impossible, many cases of bronchopneumonia with lobar consolidation appearing in the post-mortem room with a diagnosis of croupous pneumonia; (3) that on account of this difficulty statistics based on diagnosis alone are quite untrustworthy; and (4) that the mortality in croupous pneumonia is largest in the first year of life (25 per cent.), is considerable below the age of two years (15.4 per cent.), but for children above this age is comparatively small (2.3 per cent.).

**Note on a Case of Spurious Hydrophobia.**—W. S. Harrison records the case of a Russian student, aged twenty years, who was bitten on the left thumb, and who, one week later, commenced to manifest the usual symptoms of hydrophobia. The short period of incubation, however, made this diagnosis impossible, the absence of any previous rabic infection being assumed. Further investigation showed that there had been no premonitory symptoms, such as headache or pain in the limbs or thumb. The attack had developed with unheard of rapidity, so that, in two hours from the commencement, the patient was in the condition of a true case on the second or third day of his illness. It was noticed that the pharyngeal spasm did not spread into one of the respiratory muscles, and there was no true general tetanoid convulsion such as one sees in the height of hydrophobia. The examination of the throat with the aid of a tongue depressor, an almost impossible and certainly cruel proceeding in the case of a true hydrophobic, was made with ease, and it failed to excite any pharyngeal spasm. When the patient did succeed in getting some water into his mouth it was not rejected. In view of these facts it was considered that the case was almost certainly one of lyssophobia, or spurious hydrophobia, probably excited by the patient's brooding over the bite which he had suffered and its possible consequences. He recovered under simple sedatives.

**A Case of Chloroma with Clinical History and Account of Post-mortem Appearances.**—The patient of E. Trevithick was a girl aged thirteen years. The most prominent clinical features of the case were pallor, proptosis, broadening of the face due to hard swelling in the temporal regions, hard, freely movable tumors in both breasts, periosteal nodes on the sternum and ribs, and subcutaneous hemorrhages. The blood was first examined three weeks before death. There was then great increase of white cells. No actual count was made, but on comparing the films made at this time with those prepared shortly before death it was evident that the number of white cells in the blood increased very rapidly. The change, in fact, resolved itself into an enormously great and rapid increase of mononuclear cells. The author acknowledges that no definite diagnosis was made *intra vitam*, but the autopsy revealed multiple deposits of bright green material: (1) connected with various bones; (2) in lymphatic glands; (3) in the kidneys; (4) in the liver; (5) in both ovaries; (6) in the pancreas; (7) in the thyroid; (8) in the dura mater; and (9) in the choroid plexus of the lateral ventricles of the brain. The alimentary tract was free both from green pigmentation and from any obvious new formation In the right cavities of the heart was a curious looking greenish, semi-translucent blood clot. Under the microscope, sections from the various areas showing the greenish deposit showed an extensive cell-invasion. The explanation of the origin of the color of the cells is difficult. The author finds analogies in the blueness at times found in the sweat and urine. Two points from the history of the case are suggestive: First, an exceedingly obstinate inertia of the bowel; and second, a previous severe attack of pharyngitis from which the patient made a slow recovery. There must have been, the author surmises, some poison in the circulation which stimulated a great overgrowth of certain tissue-units which eventually led, by a misplaced activity, to the death of the host.

*British Medical Journal, July* 18, 1903.

**Treatment of Pleural Effusion.**—Henry Waldo, since using with success a dressing soaked in a saturated solution of common salt as an application to joints affected with osteoarthritis, has tried the same plan of treatment in pleurisy with effusion of clear serum. The results have been most happy.

**A Note on the Treatment of Chorea by Ergot of Rye.**—Eustace Smith declares that ergot of rye can be given to children in large doses without risk of harm. As a sedative to the nervous system its value is great. In all cases the ergot should be pushed till it produces a beneficial effect. The remedy ought not to be left off directly normal control over the muscles has been restored, but should be continued as long as any abruptness of voluntary movement remains.

**Impressions of the Efficiency of Professor Dunbar's Antitoxin in Hay-fever.**—Felix Semon declares that different people react surprisingly differently, and also in one and the same person the effects of the remedy in some instances vary from day to day without a satisfactory explanation. As might have been anticipated from the nature of the affection itself, in which, during the critical time, almost constant reinfection takes place, the remedy in its present form of application is not curative. Whether this end will be attained or not, remains to be seen. The remedy has given relief in some cases and has acted beneficially in postponing the occurrence of the attack in others.

**The Problems of Cancer.**—E. F. Bashford declares that biological investigations will probably ultimately form a very important aspect of the study of cancer. There can be no doubt that some, if not all, forms of malignant new growths occurring in man and animals are identical in nature. The possible importance of the study of age-incidence as a feature in a general biological inquiry has not hitherto had attention drawn to it. A comparative study of the age-incidence of cancer among domestic and wild animals will give comprehensive information on the relation of the incidence of cancer to the rapidity with which maturity is attained. Light may also be thrown on the reasons underlying the higher cancer-rate of later life. A study of age-incidence in males and females of differing races is desirable. Another specific problem—deciduoma malignum—requires consideration from the comparative biological standpoint. The prevailing pessimistic views as to the hopelessness of investigating cancer are unjustified in the face of what still remains to be done in this problem.

**Erythemata as Indicators of Disease.**—James Galloway considers this group of eruptions under two groups: the simple erythemata, the result of hyperæmia, transient as a rule, and productive of no permanent change in the skin; and the exudative erythemata, resulting from hyperæmia, transudation and exudation, as well as from actual inflammation, which cause skin changes which are apt to last long or even be permanent. In the first class, the most characteristic example is ordinary flushing. Various vascular disturbances are nearly related to this condition. If there is a considerable amount of diminution in the peripheral vascular tension, a certain degree of tachycardia may naturally be expected. Again, there may be grave disturbances of nutrition. Simple erythemata may develop nodular and necrosing lesions, and these may arise quite apart from tuberculous causation. In the second class the writer first discusses protozoal infections. In the cases of trypanosomiasis seen by the writer the eruption was general, but affected the back of the trunk and the face in a marked degree. The most common cause of the forms of blood poisoning which gives rise to exudative lesions of the type of erythemata multiforms are the toxins produced as the result of improper food, or of its imperfect digestion or elaboration in the tissues. A few cases are noted of severe erythemata multiforme occurring in connection with Bright's disease. The writer thinks that the histological evidence from examination of lupus erythematosus lends no support to the tuberculous theory of its origin. The cause he regards as a toxæmia arising from various sources.

*Münchener medicinische Wochenschrift, June* 30, 1903.

**Hæmolysis in Experimental Infections.**—Oskar v. Wunschheim has undertaken experimental work, and thus far has limited his studies principally to anthrax infection. Rabbits inoculated with anthrax bacilli nearly always show a hæmoglobinæmia which is very intense, and first appears, suddenly, a few hours before death. The blood serum becomes very dark and may be designated as "serum pupureum." The appearance of this hæmolysis does not correspond with the time of the appearance of the microorganisms in the blood, since the latter precedes the former by several hours. The bacillus of hen cholera produces the same effect in the rabbit but not in the hen. Negative results were obtained with Fraenkel's diplococcus. Hæmoglobinuria was never observed. The location of the production of the lysis is problematical. The reason for the non-appearance of hæmoglobinuria is probably to be sought in the capacity of the liver to transform the hæmoglobins set free by the hæmolysis into bile pigments, which are excreted in the urine and appear in abundance there. Only in the presence of a marked excess of hæmoglobin would it appear in the urine, and it is probable that the death of the animals occurred before this took place.

**Antistreptococcus Serum and Its Employment in Man.**—Menzer, by experimentation, concludes that antistreptococcus serum acts in man as in animals by producing a phagocytosis, so that the chief rôle in the fight with the streptococcus falls to the body cells. Therefore, if for any reason the body is unable to answer to this call the employment of an antistreptococcus serum is useless. In addition to the destruction of the infecting agent, the body must subsequently reabsorb the destroyed bacteria and body cells. For this reason, when circumscribed collections of pus are present, antistreptococcus serum is contraindicated unless such collections are surgically evacuated, for without this the injection of the serum would favor the absorption of the poisonous constituents of the circumscribed pus. The best results are obtained in acute septicæmia (streptococcus infection) by using the serum early and in large doses. For medicinal use only those sera should be used which have been obtained from streptococci recently isolated from human beings. Since the unity of species in streptococci has practically been established, the actual province of the streptococci used need not be considered. The testing of a streptococcus serum on animals does not show its efficiency for man, and at present the only measure of its power is to be obtained from its effect upon human beings.

**Tabes and Traumatism.**—Windscheid thinks that the recent tendency in some quarters to regard traumatism pure and simple as a cause of tabes is to be viewed with much suspicion. There is no doubt but that the primary lesions of tabes are to be found in the spinal cord, and that all other lesions present are to be regarded as secondary. Furthermore, such primary lesions are undoubtedly caused by the action of toxins. Whether or not such toxins must be syphilitic has not been as yet definitely decided, nor does such a question enter into the discussion of the present question. Traumatism may be divided into three varieties, according to the location to which it is applied: (1) Traumatism directly applied to the spinal column. (2) Traumatism of the head. (3) Traumatism of the body. Traumatisms of the first variety are frequent, but the subsequent development of tabes following them is very rare. If such traumatisms could in any way act directly as a cause of tabes it is certain that tabes would follow them with much greater frequency than statistics show. It is inconceivable to suppose that traumatism of the head could be the sole causative agent in such microscopical lesions of the spinal cord as primarily occur in tabes. It might be supposed that traumatism of the extremities might give rise to an ascending neuritis, which would subsequently involve the posterior spinal roots and produce the clinical picture of tabes. This would be plausible except for the fact that much research has shown that in all cases of tabes examined the spinal lesions are primary and not secondary. From these considerations it is hence seen that it is irrational to suppose that traumatism pure and simple can ever give rise to tabes. It is, however, not only possible but probable that, as a secondary and contributing factor traumatism may play an important part in the development of this disease. Many cases are on record in which traumatism in syphilitics was followed by tabes, and it is well within the range of possibilities that the causative toxins, being present in the system, may first exert their harmful influences upon the spinal cord, when the resistancy of the same is reduced as the result of traumatic influences.

*Deutsche medicinische Wochenschrift, July 2, 1903.*

**Surgical Treatment of Ascites in Cirrhosis of the Liver.**—D. G. Zesas gives the indications for Talma's operation, together with a critical review of the same. There can, of course, be no question but that the most favorable and permanent results are to be obtained by operating as early as possible after the development of the ascites. All cases which are thus operated upon, however, do not show a permanent disappearance of the ascitic fluid. A case is here reported in which the ascites first appeared in March. Operation was done according to Talma in the following July. The ascitic fluid rapidly re-accumulated and resisted further treatment although the general condition was somewhat improved.

**An Acute Trophoneurotic Affection of the Entire Lower Extremity.**—E. Grawitz's patient was a female seventeen years of age. The personal and hereditary history was good, with the exception that she had suffered in childhood from slight anæmic and hysterical appearances. The present illness began suddenly with pains in the left lower extremity, there having been no previous history of injury. These pains began in the sole of the foot and quite rapidly ascended upward. Stomach disturbances with more or less vomiting soon developed. Upon examination the left lower limb was perceptibly reduced in circumference over the right and was of a dark red color. The following facts show that the affection is not to be ascribed to a venous stasis: (1) The reduction in the size of the involved limb. (2) No molecular concentration of the blood taken from the left lower limb over that taken from the right. (3) A general atrophy of the skin of the left lower limb. The only portions of the involved limb which did not show the appearances described were the toes and the sole of the foot. The bodily temperature has been normal throughout, and that of the skin of the involved limb has been the same as that of the remaining portions of the body. It is evident that this case must be included among the trophoneuroses, but that it does not correspond in its entirety with any of those which have previously been described. It most nearly approaches a form described by F. J. Pick under the name "Erythromelia," but there the cutaneous atrophy was insignificant as compared with the case here reported.

*Münchener medicinische Wochenschrift, July 7, 1903.*

**The Massage Treatment of Recent Fractures.**—Jordan, from an experience of seventy-three cases, says that massage and mobilization may be employed in all fractures of the upper extremity. Here, massage followed by fixation, may be employed in joint and shaft fractures which are not accompanied by marked dislocation. In shaft fractures with marked dislocation, with great tendency to recur, massage and permanent fixation until union are to be employed. In fractures of the lower extremity the use of massage is to be limited to joint fractures and employed in combination with walking bandages. In shaft fractures it is only to be recommended as a preparatory measure.

*French and Italian Journals.*

**The Treatment of Tuberculous Adenitis.**—An editorial sums up the treatment of this affection as follows: If a patient merely present a few ganglia that are simply hypertrophied, medical treatment will nearly always overcome the trouble. If the disease continue to develop they must be removed. If there be benign lymphadenoma, extirpation is the best procedure. If there are caseous ganglia, one may experiment with injections, but one is nearly always obliged to have final recourse to surgery. If the sacs have turned into abscesses, the best results are obtained by evacuating puncture, followed by healing injections. Ganglional masses complicated by fistulæ should be extirpated.—*La Tribune Médicale*, June 27, 1903.

**Treatment of Nephritis by Reduction of Chlorides.**—Fernand Widal and Adolphe Javal conclude from their researches into the pathological physiology of œdema, hydration and albuminuria in epithelial nephritis, that a temporary treatment by the reduction of chlorides is the best at certain stages of the disease. Milk is of especial benefit by reason of its poverty in chlorides. Other substances, even foodstuffs rich in albuminoids, as meat, or in carbohydrates, as bread, sugar and potato, or in fat, as butter, together with rice and pastries, may be taken with even more confidence than milk, provided that no salt be added. These substances contain the least possible amount of chlorides, even less than milk.—*La Presse Médicale*, June 27, 1903.

**Adrenal Extract in Hemorrhoids.**—A. Breton has used this remedy in the treatment of hemorrhoids. The patients were affected with prolapsed or non-prolapsed hemorrhoids, reducible, but bleeding profusely. Fifteen to twenty minutes before going to stool the patient introduced just within the anus (not into the rectum) a tampon of absorbent cotton impregnated with a 1 to 1,000 solution of adrenal extract. From the very first application the hemorrhages ceased. After five or six treatments the hemorrhages were entirely stopped, and in some cases the prolapse was cured. In the case of hemorrhoids situated high up in the rectum suppositories containing the drug have given good results.—*Gazette des Hôpitaux*, June 30, 1903.

**Otitis Media and Externa.**—Mario Molinari, from his studies on the subject, holds that otitis is always, or nearly always, due to the action of microorganisms, usually an association of them, so that it is not possible to state which special one, if any, is capable of causing the morbid process. As to treatment, his practice is to remove the purulent discharge daily by abundant and hot irrigations of a three-per-cent. solution of sodium bicarbonate, followed by one of hot sterilized water. The auditory canal is then dried with tampons of absorbent cotton and finely pulverized boric acid introduced without pressure. Gauze, soaked in a boric solution, is applied to the external ear. His results have been of the best.—*Giornale Medico del Regio Esercito*, June 30, 1903.

**Massage and the Treatment of Hemorrhoids.**—A. Cuche thinks it very doubtful if constipation should be given the prominent place in the etiology of hemorrhoids which

has been accorded to it. The author recommends a daily massage of the anus and the sphincter by introducing the finger about an inch above the sphincter immediately after a movement and working the muscle for about half a minute. This procedure is sure to bring relief, and in time a cure. The earlier in the disease this treatment is applied the more certainty is there of its success. If the hemorrhoids are due to digestive troubles of the large intestine, daily massage of the abdomen, lasting twenty minutes, will be useful.—*Tablettes Médicales Mobiles*, July 1, 1903.

**The Danger of Administering Sodium Chloride to Patients with Bright's Disease or Cardiac Affection with Threatened Anasarca.**—M. J. Courmont recalls the fact that the equilibrium of molecular "isotonia" in the system is maintained by the elimination of ingested salts by the emunctories, these salts having become hypertonic attract the watery part of the serum and cause œdema. When, therefore, the kidneys become impermeable to sodium chloride, this substance passes into the tissues and causes œdema. Hence, if a patient have reached the stage of dropsy it is dangerous to let them take salt unless the kidney largely eliminates it. Injections of artificial serum may thus become elements of great danger.—*Lyon Médical*, July 5, 1903.

**A Case of Late Contagion of Scarlet Fever.**—M. R. Millon reports the case of a boy who was affected with scarlet fever, contracted probably at school. His younger brother was at once sent away from home. The patient went through the various stages of the disease, after which disinfection and destruction of every possible source of contagion was carried on to a degree that seemed almost extreme. The younger child returned after forty-five days of absence, and the very next day was seized with a typical attack of scarlatina. These facts prove that the contagious period of the disease is much longer than is usually supposed. It is also worthy of note that in spite of the most minute and rigorous disinfection, the agent of the disease was not totally destroyed.—*Journal de Médecine de Paris*, July 12, 1903.

**Menstrual Epilepsy Treated by Ovarian Transplantation.**—M. Brennan reports the case of a girl of nineteen years, who for three years had attacks of epilepsy at or near her menstrual periods. No lesion of any kind was discovered. No form of medical treatment succeeded in overcoming the difficulty. It was finally decided to operate; the uterus was found to be normal, the ovaries also, with the exception that they were somewhat cystic. The ovaries were removed, and a portion of one of them, as large as a bean, deposited in a cavity prepared to receive it on the fundus uteri, and uterine tissue brought together around it. The patient made a good recovery, has menstruated but once, eight weeks after the operation, and has had only a few very slight nervous attacks, and these only following special overexertion. The improvement is so great that there is every reason to hope for a complete cure.—*La Revue Médicale*, June 17, 1903.

**A New Symptom Observed in a Case of Adams-Stokes Disease.**—Agenore Zeni describes a curious symptom, which consisted in a perfect synchronism between the respiration and the pulse beat. The ventricular contraction occurred only in coincidence with the respiratory act, and in fixed relation to it, that is to say, inspiration very slightly preceded the cardiac systole. This occurred, not as temporary phenomenon, but with regularity. The author holds that this is a new symptom of the disease, and that it is due to the fact that the moderating center of the heart is dependent upon the regulating center of respiration, and that the tonicity of certain inhibitory fibers of the vagus are lowered. In other words, during inspiration the activity of those fibers of the vagus which prevent the progress of the contractile wave through the various portions of the heart, is diminished or abolished.—*La Riforma Medica*, July 1, 1903.

**The Treatment of Burns by Topical Vegetable Applications.**—M. Liégeois gives a number of remedies which may be used in the country where one is unable to obtain carron oil, picric acid, and the various other chemical substances in use for the treatment of burns. In burns of the first degree, without blister, a crushed raw onion, over which has been scattered a little salt, will often take out the pain. Ambroise Paré, in burns of the second and third degree, after having opened the blisters, used to apply slightly salted nut oil in which elder leaves had been cooked. The bark and the inner bark of the elder have both been recommended in the case of burns. Crushed sage leaves are healing. Ivy has always enjoyed a reputation for its healing qualities in wounds, and our ancestors used to make a marvellous pomade by cooking the juice recently expressed from its leaves with goose oil. Nut oil and red wine in equal parts, say 250 grams each, with four grams of the fresh root of aristolochia, cooked until the wine has completely evaporated, calms the pain instantly and assists cicatrization.—*Journal des Praticiens*, July 11, 1903.

*Annals of Surgery, July*, 1903.

**The Surgical Features of Perforation of the Intestine in Typhoid Fever in Children.**—C. A. Elsberg reports a successful operative case, the patient being a girl of six and one-half years. On the thirty-third day of the disease there were symptoms of perforation and operation was promptly performed by Dr. Lilienthal. Elsberg reviews the literature of this complication of typhoid fever in children, and finds that it occurs with about the same frequency as in adults. A careful analysis is made of the histories of twenty-five operative cases in children chosen from a list of 289 operative cases at all ages. Of the twenty-five there were sixteen recoveries. Figures show that the chance of recovery after operation is about twice as great in children as in adults. The author closes his paper by stating that he has attempted to show: (1) That perforation of the intestine in the course of typhoid fever is very nearly as frequent in children between the ages of six and fifteen years as in adults. (2) The symptoms do not differ essentially from those of adults. (3) Although recovery may, in exceptional cases, take place without operation, the treatment should be a surgical one as soon as the diagnosis has been made. (4) The prognosis after operation is more than twice as good in children as in adults, and very early operative interference offers the best chances for recovery.

**Three Successful Laparotomies for Intestinal Perforation in Typhoid Fever.**—The cases are reported by R. H. Harte. In the first case, male, twenty-nine years, the perforation occurred during the middle of the disease with the patient in good general condition, was immediately recognized and operated on with some delay, however, owing to refusal of consent of relatives to surgical intervention. The second case, male, thirty-nine years, was of the ambulatory character, coming on suddenly in a patient who was not much exhausted from the effects of the disease, and presenting many of the characteristic symptoms of an acute appendicitis with perforation. This class, says Harte, is decidedly the most favorable for operation, and from it the greatest number of recoveries will be gathered. In the third case, male, thirteen years, the vital energies were almost entirely exhausted, as the result of a prolonged and exhausting disease. It is in these cases that the greatest difficulty is experienced in arriving at an accurate diagnosis whether perforation really does exist or not. The author enumerates the general rules of diagnosis, and says that the two important factors to be insisted on are first, the early recognition of the lesion and dealing with it as rapidly as possible, in order that as little time as possible will elapse from the time of perforation until operation has been performed; and, second, that the operation should be so planned, since time is so important an element, that not a moment should be wasted during it, the technique being of the simplest character, as every moment of delay will cause a much higher percentage of mortality.

**Dislocation of the Carpal Scaphoid.**—The patient of L. W. Ely was a man of twenty-five years, whose wrist was caught under an overturned automobile. The injury was at first considered as a crushing of the tendons and hot applications were prescribed. When seen twenty-four hours later by the writer the wrist was swollen and infiltrated, and presented on its flexor aspect a number of abrasions, showing the nature of the violence—that is, direct. Motion or pressure caused pain. The case appeared to be a Colle's fracture, and the patient was told that he must take an anæsthetic and have it reduced. The operation was done that afternoon. Under ether, crepitus could be distinctly perceived in the wrist, though its origin could not be easily ascertained. By manipulation, the scaphoid could easily be dislocated on the dorsum of the wrist, and by pressure could be replaced. On this symptom the diagnosis was made. A skiagram taken at a later date showed a slight tipping forward of the scaphoid and a chipping off of the styloid process of the ulna; but there is doubt whether the lesion was a simple dislocation of the scaphoid, or whether it was accompanied by a fracture of this or of one of the neighboring bones. The skiagram showed no such fracture, but the crepitus seemed to come from a point very near the scaphoid. The dislocation, however, was unmistakable. The treatment was by anterior and posterior molded plaster-of-Paris splints, the posterior splint reaching to the end phalanges, the anterior to the metacarpophalangeal joints. At the end of one week the anterior splint was removed, and at the end of about three weeks the posterior splint was taken off, and adhesive tape was applied to the forearm and hand. This was left on for about two weeks, permitting some motion, but affording a certain amount of support. The patient recovered with a good degree of motion in all directions.

# Society Reports.

## BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held at Swansea, July 28, 29, 30, and 31, 1903.*

**Special Cable Report to the Medical Record.**

GENERAL SESSIONS.

TUESDAY, JULY 28—FIRST DAY.

THE seventy-first annual meeting of the British Medical Association was held this year at Swansea, in Wales. As usually happens when this great association meets in any but the largest of the provincial towns, every available hall was utilized for places of meeting of the general body, the various committees, and the eleven sections. Even the public library was captured and converted into a huge office for registration and common assembly, and here also was installed the annual exhibition of drugs, instruments, and other medical appliances, together with the pathological museum. The attendance was fairly large and representative.

**Induction of the New President.**—The first general meeting was called to order on Tuesday afternoon by the retiring president, Mr. Walter Whitehead, F.R.C.S. Ed., F.R.S.E., of Manchester. He introduced, with a few complimentary words, the president-elect, Dr. Thomas Dryslwyn Griffiths, M.R.C.S., of Swansea, who took the chair amid loud applause.

**Election to Honorary Membership of the Prince of Wales.**—After expressing his thanks and the deep sense of honor which he felt in having been selected for this exalted position, he said that he had a most pleasing duty to perform in announcing that His Royal Highness, the Prince of Wales, had intimated that honorary membership in the British Medical Association, which had been tendered to him, would be most acceptable. The Prince, like his illustrious father, had always shown great solicitude for the physical well-being of his future subjects and had invariably manifested the deepest interest in all matters pertaining to public health. It was therefore fitting to elect him to honorary membership in the representative medical body of the United Kingdom, and especially appropriate to do so at this meeting held in the province of Wales whence the Prince derived his best known title. Dr. Griffiths, therefore, moved the election as an honorary member of the British Medical Association of His Royal Highness, the Prince of Wales, and he did so in view not only because of the honor this membership would confer upon the association and upon the medical profession in the United Kingdom, but also in recognition of the distinguished services His Royal Highness had rendered to the science of medicine and of public health. The nomination was seconded by Dr. Andrew Clark, F.R.C.S., of London, and the election was carried by acclamation with cheers and the singing of "God Bless the Prince of Wales."

A vote of thanks was passed to the retiring president, Mr. Walter Whitehead, for the able services he had rendered as presiding officer of the association during the past year, and the motion was offered and carried to elect him a vice-president for life.

**The Report of the Council** was then presented by the chairman, Mr. Andrew Clark of London, and, after some discussion, was adopted. In the report satisfaction was expressed at the honors which had been conferred upon several members of the association, Sir Patrick Manson, and others. The treasurer's report of the income and expenditures for the year was then presented, and announcement was made of a number of grants to cover the expense of special committees and for scientific research. The total amount appropriated by the association for scientific research in the last thirty years, that is to say, since 1874, was about £18,000, in addition to some £2,000 granted to societies and other bodies working independently of the association.

In the discussion that followed the presentation of this report, Dr. Robert Bell of Glasgow found occasion to criticise quite severely the financial statement, and said that the manner in which the accounts were kept was most unbusinesslike. The methods of the council were defended by other speakers, and eventually the report was adopted as presented, except that an additional appropriation of £300 was made to the Sir Charles Hastings superannuation fund. The meeting then adjourned until evening.

**Address of the President.**—At the adjourned meeting in the evening the new president Dr. THOMAS DRYSLWYN GRIFFITHS delivered his address, taking as his subject "Evolution in Surgery." He spoke of the reciprocal influence of the three sciences of surgery, bacteriology, and therapeutics, and discussed the way in which existing medical knowledge could be further applied so as to benefit mankind in future years. He drew a most striking picture of hospitals as now constructed and conducted and compared them with those of fifty years ago. Cleanliness, sunshine, and free ventilation are now the characteristic features where formerly sepsis, crowding, and stagnant air prevailed. Not only were the principles of surgical asepsis unknown, but even isolation of those ill with what are now known as infectious diseases was often through ignorance neglected entirely or carried out so imperfectly as to be worse than useless. The wonderful transformation which had taken place in the surgical wards was due entirely to the influence of what the world has called, after the great discoverer of the nature of surgical sepsis, listerism. This term was used to cover all surgical methods based upon a recognition of the fundamental fact that the natural healing of wounds takes place only when the exposed and absorbent surfaces are protected against deleterious microorganisms. The principles of listerism could be applied with the greatest certainty of success in well-appointed modern hospitals by surgeons and nurses trained in the practice of aseptic surgery and with every facility at hand for attending to the details of the method. Through these hospitals the very poor were able to enjoy the benefits of skilled aseptic treatment. In the homes of the rich also it was comparatively a simple matter to provide the necessary assistants and appliances, since that was only a question of expense. But the application of listerism, or of antiseptic or aseptic surgery, as some preferred to call it, to the needs of the middle classes—of those in moderate circumstances who were too well off or too self-respecting to avail themselves of the free treatment accorded the very poor in hospitals and too poor to command the costly assistance procurable by the wealthy, was inferior and left much to be desired. For the needs of such the speaker advocated the establishment of what he called "Listerian homes," small surgical establishments not sufficiently large to deserve the name of hospital or even of infirmary, but sufficiently well appointed to meet the requirements of aseptic surgical practice. These establishments should be numerous and so distributed throughout the country as to be readily accessible to all in need of them. They could be founded by private beneficence or by public subscription, and could be placed at the command of all needing the conveniences they offered at moderate cost.

Leaving then the subject of surgical evolution, Dr. Griffiths discussed matters relating to public health. The application of modern medical knowledge in this domain, he said, had not kept pace with the progress in medicine and surgery. The mortality among children under one year of age had actually increased, yet the greater number of these deaths were due to preventible causes. Even the very moderate improvement recently effected in the sanitary laws had brought about an actual saving of sixty thousand lives in this country. The speaker advocated the formation of a public health service, the officers of which should be under the orders of the president of the local government board. The establishment of such a service would not be difficult, for a nucleus already existed

in the employment of medical men for special duties by various local authorities. If such a service could be established it would grow in importance and value to the community, and eventually it would be one which would offer an enviable career to men of the highest scientific attainments.

The end and aim of all sanitary science was the prevention rather than the cure of disease, and consequently, to speak of the crusade against tuberculosis only by way of illustration, while sanatoria and their like were all very well in their way, and indeed of the highest utility, the proper mode of combat was to go to the beginnings, to attack the evil at its roots. This was to be brought about by education of the people and by inculcating in them, by means of public lectures, the newspapers, and the like, the virtues of a general attention to hygiene and of a care for healthy homes.

The enormous success of the British Medical Association, which now counted in its ranks over 18,000 members, medical men from all parts of the United Kingdom, had brought with it corresponding responsibilities and power. One of the ways in which it was most desirable that it should meet that responsibility and exercise that power was by guiding and influencing Parliament and the various municipal and other public bodies in the matter of public health legislation. Not only could the enactment of vicious laws—that is to say of laws prejudicial to public health—be prevented, but the wise counsels of experienced sanitarians might result in legislation in certain matters which would work in the direction of the highest good and in a vast improvement in the health of the entire nation. Such a consummation was devoutly to be hoped for, and such it was within the power of the united medical profession of this land to bring about.

**Award of the Stewart Prize.**—Announcement was made that this prize, of the value of £50, had been awarded to Dr. Fred. Walker Mott for an essay embodying a report of researches made to determine the causes and devise means of prevention of dysentery in asylums.

On motion a vote of thanks was unanimously accorded to the President for his scholarly and practical address, and after other motions conveying the thanks of the association to the authorities of Swansea for their kindly reception, the meeting was adjourned.

**American Visitors.**—Among the Americans present from the United States were Drs. J. H. Edwards of Wylam, Ala., E. S. Foster of Boston, W. A. Gowing of Toledo, M. H. Gill of Hartford, and F. D. Sanger of Baltimore; from Canada, Drs. J. G. Adami and George Armstrong and Sir William H. Hingston of Montreal.

### WEDNESDAY, JULY 29—SECOND DAY.

The association met in second general session on Wednesday evening with the President, Dr. T. W. Griffiths, in the chair. The only title of importance on the program was the

**Address in Medicine.**—This was delivered by Dr. FREDERICK T. ROBERTS, Senior Physician to the University College Hospital and Holme Professor of Clinical Medicine in the University College, London. He said he had chosen as his theme one of the most important of all the subjects with which the modern physician had to deal, namely "Infective and Infectious Diseases." In this field, he said, the most startling and brilliant discoveries and those having the greatest influence upon the health and happiness, and therefore the progress of the human race, had been made, and it was here that was demonstrated in the most striking manner how remarkable had been the practical advance in scientific medicine during the last quarter of a century. But rich in discovery and scientific progress as had been the past, the future promised even more and greater developments, and rash would be the man who would put a limit to the benefits to accrue to the human race from the studies and experiments of the workers in this inexhaustible mine.

He would make a distinction, he said, between the two qualifying words used in the title of his address, for it was to be noted that the terms "infectious" and "infective" were not synonymous, the former denoting specifically that the disease so designated was capable of being communicated directly from person to person, or from some other animal to man. The infective diseases were equally due to the presence of pathogenic organisms, but were not so directly contagious or transmissible from the body of the sick person to a second susceptible individual. The morbid phenomena of each and every one of the diseases included in these two groups were the direct result of the action upon the body of one or more living microorganisms. Experiments and clinical experiences without number had demonstrated beyond the shadow of a doubt that the pathogenic microorganisms were possessed of a specific and individual activity, that is to say, that each microorganism possessing pathogenic properties was capable of setting in motion a morbid train of symptoms belonging to one disease entity and to no other.

Although it was only within the memory of men not yet past the middle of life that positive proof of the bacterial origin of many infective and infectious diseases had been furnished, the phenomenon of contagion had long been recognized and acted upon in the isolation of the sick. The number of contagious diseases which had definitely been shown to be dependent upon the vital activity of some demonstrable microparasite of either the animal or the vegetable world was already large and was constantly being added to, the list having been materially lengthened as the result of certain quite recent investigations. But the remarkable fact was to be noted that even now, in spite of all the resources of modern scientific research, there were many diseases known beyond doubt to be infectious, some of them, indeed, among the most common and the most studied, in which the specific microorganism had not yet been recognized. In most of these cases the certainty of the existence of some causative microparasite, either bacterial or protozoan, was practically absolute, but at present the physical proof was lacking. This was puzzling and a stimulant to further research, but it need not be crippling to those having to do with the management of such diseases, for we were amply justified in the confident assumption that some pathogenic microorganism did exist in each of those cases, and in using such belief as the basis of a sound working hypothesis.

Among the diseases now ranked, according to modern views, as infective, were pneumonia and acute rheumatic fever. Bacteriology had further proved conclusively that several previously unsuspected diseases were certainly infective, or even infectious. Among those the most worthy of remark were tetanus, tuberculosis, and malaria. It was impossible for the white races to evade certain responsibilities which were the necessary results of following out the so-called imperialistic sentiment, among which were those regarding the control of the terrible tropical or subtropical diseases. While on this subject he would call the attention of his hearers to the intelligent patriotic efforts of Sir Alfred Jones to promote the study of diseases of Southern climes in their home within the tropics.

Referring to the relative degree of infectiousness of the various diseases of the group under discussion, Dr. Roberts spoke of the curious fact that tuberculosis was at the present day regarded as one of the most virulently infectious diseases, equal to, if not surpassing, in this respect, even smallpox and scarlet fever. This idea was, of course, absurd, yet it had taken such firm root in the minds of many even well-informed persons among the laity that there was danger of its doing an infinite deal of harm in several ways. This widespread belief in the infectiousness of tuberculosis was without a doubt due in great measure to the crusade against the disease which had

been inaugurated some years ago, and since carried out with such energy by conscientious workers in all lands. While not relaxing their efforts looking to the eradication of this scourge of mankind, the workers should take care not to allow false notions of the nature of the disease to be propagated, for this would tend only to increase the misery of those already suffering from a distressing malady.

Typhoid fever was another disease which had until recently been regarded (and the belief had been practically acted upon) as not of infectious nature and consequently free from the dangers of personal contagion. Nowadays, however, there was a growing objection to the admission of typhoid patients into the wards of general hospitals, instances of apparent communication of the disease to others in the same ward having been more than once noted. As regards smallpox the danger of infection through the atmosphere was well established and practically recognized, but how far the contagious principle could be carried in the air from a smallpox hospital or from a hospital ship harboring smallpox patients was a matter which had not yet been satisfactorily ascertained. The determination of this point was, however, a matter of very great moment, for the uncertainty at present existing might have troublesome and even exceedingly grave consequences. The speaker had frequently read in medical literature the most contradictory opinions on this point expressed by men whose experience had apparently been such as to warrant them in speaking authoritatively.

Regarding certain diseases, it was absolutely true that infection could be and was spread through the medium of drinking water and food. Even in respect to tuberculosis, it could not be doubted, despite Koch's dogmatic negative statements, that the affection could be spread through the agency of the milk and meat of diseased animals. Recent investigations in this country had proved very conclusively that this investigator, despite his high scientific claims and his recognized right to speak with authority, was in this regard entirely wrong. It would be a very great error and one fraught with the gravest consequences to act on Koch's view or to ignore in the smallest particular the possibility of the conveyance by milk of the infective agents, not only of tuberculosis, but of other diseases as well.

Another mode of the spread of infectious diseases was the conveyance of the microparasites by animals, such as shellfish. There unfortunately could be no doubt that oysters were not infrequent and most potent agents in the propagation of typhoid fever. Recent investigations had also proved with absolute certainty the rôle played by insects in spreading various diseases.

Still another agent in the transmission of disease was man himself. It was well known that every one carried in the mouth and other parts of the body vast numbers of microorganisms which were ordinarily innocuous—at least to the host while his susceptibility to the particular disease which they represented remained in abeyance, but which might under favoring conditions become extremely virulent either to himself or to others. A man might thus infect his susceptible neighbor at any time while he himself went scot free.

Dealing with the question of the prevention of infection the orator admitted that we could as yet boast of very few specific remedies, and additions to the list were rarely recorded. He cautioned his hearers against looseness of speech and a too cheery optimism in the way of making promises and predictions which from the very nature of the case were in great danger of never being fulfilled. Any one recognizing the want of unanimity regarding the causation and very nature of many of these diseases could but confess that it would be most rash to speak of presumptions as if they were facts. But while caution in this respect was the part of wisdom, we should never relax our efforts to promote the good cause and to encourage those engaged in the slow and laborious and often thankless task of investigation. The duty of the medical profession was to second every measure, scientific or practical, which had for its aim the mitigation or eradication of those widespread and often terribly fatal infectious diseases which now played such a preponderating rôle in the increase of the death rate, and which, even in cases of recovery, left such serious and often irremediable sequelæ among large numbers of the community. These things it was the duty of the profession to do, despite the vicious attacks of those who would impugn their motives. There were numerous "antis" hovering about on the outskirts of the medical army, but for downright impudence and insolence the "antivivisectionists," so called, held the field. The hysterical outbursts of these impotent mouthers should be treated with the silent contempt which they deserved, and soon nothing more would be heard from them.

On motion, a vote of thanks was rendered Dr. Roberts for his interesting and instructive address on a topic of such vital importance to mankind.

Just as the session was about to be adjourned the president read a telegram received from the Prince of Wales warmly thanking the association for the honor of membership which had been voted him, and accepting the same with great pleasure.

### SOME OF THE WORK IN THE SECTIONS.

Most of the section meetings were held in the rooms of the Higher Grade School and the Swansea Grammar School.

**The Vaccination Acts and Smallpox Prevention.**—In the section on State Medicine the discussion on this topic was opened by the president, Dr. JOHN C. MCVAIL of Glasgow. He supported the contention of the Medico-political Committee of the British Medical Association that revaccination be made compulsory, advocating the passage of a law fixing the period at which the second vaccination is to be performed between the ages of ten and thirteen years. He said that the same provisions regarding the nullifying effect of "conscientious objection" should be operative in the case of revaccination as were now in regard to primary vaccination, but he held that the clauses granting exemption from the provisions of the act should be more definite than they were in the existing act. Regarding future legislation, he suggested that the law should entrust carrying out the provisions of the act to a specially constituted local government board. Vaccine lymph could be supplied by the government or by private manufacturers under government supervision and guarantee. The speaker said the Section on State Medicine should urge upon the council of the association the importance of using all the machinery of the British Medical Association in order to bring before the members of Parliament the extreme necessity of further vaccinal legislation on the lines already approved by the council, modified as it might be, by suggestions adopted by the section.

The discussion was continued by Drs. DRYSDALE, GARSTON of Cheshire, and MOLE of Gower. The latter urged that the vaccination marks should be not less than four in number. Not only, he said, should vaccine lymph be provided free to private practitioners as well as public vaccinators, but all fees for vaccination should be guaranteed, and therefore, if necessary, paid by the government.

Dr. HOEDER of Cardiff said that public vaccinators were underpaid, and he urged that the legal fees for vaccination be raised appreciably.

Dr. ROBERTS of Kilmarnock said that many of the difficulties in the matter of vaccination experienced by English practitioners were unknown in Scotland. In the latter country the vaccination fee was often included in the charge for confinement. In order to avoid possible trouble and to prevent the practice of vaccination being brought into disrepute in the minds of the laity, the

physician should be sure before performing the operation that the child itself was perfectly healthy, and especially that it was not a subject of hereditary syphilis, or of some generalized skin disease.

Dr. EBENEZER DAVIS, Medical Officer of Health for Swansea, referring to the difficulties which had been experienced by the government officials during the recent outbreak of smallpox, said that his experiences during that epidemic had strengthened him in the conviction that revaccination before the subject had reached the wage-earning age was most advisable and indeed, he might say, of absolute necessity.

Dr. GARSTANG moved and Dr. ALBERT JONES seconded the passage of a resolution adopting as the sense of the Section on State Medicine the suggestions made by the president of the section in his able address.

Dr. DRYSDALE moved the adoption of a resolution expressing the belief of the Section on State Medicine that smallpox would soon become as rare in England as it now is in Germany were every infant vaccinated during the first year of life and every child revaccinated at the age of ten or twelve years.

**Legislation Regarding Midwives.**—Dr. J. WARD COUSINS of Portsmouth read a paper on the need of further legislation regulating the practice of midwifery. He said that while the proposed Midwives Act would entail a much greater amount of labor on the part of the Medical Officers of Health, it would be most advantageous in that, through its provisions, the efficiency of the midwife would be tested in a most practical way. The majority of cases of confinement needed no other supervision than that which the ordinary midwife was entirely competent to give, but the real trial of the midwife's fitness for her task came when emergencies arose. She should be able to recognize the moment when the limit of her practical knowledge and of her skill was reached, and in her ability to recognize this moment lay the real test of her efficiency. The workings of the new act would put midwives to this very test, and in so far the proposed legislation was most commendable.

The discussion that followed the reading of this paper was chiefly upon the proper constitution of the local supervising committees, and the consensus of opinion seemed to be that this committee should be composed chiefly of medical men. In regard to this point Dr. Ward Cousins pointed out that in the county councils was vested the power of appointing the local committees and also of availing themselves, when necessary, of the services of private medical practitioners. He referred to one practice which was open to serious abuses. The law which now left it to the physician to report or not, as he might see fit, the birth of stillborn children, made possible the concealment of many crimes. It would be better to make the reporting of all stillbirths compulsory.

**Medical Experiences During the Pekin Relief Expedition.**—In the Navy, Army, and Ambulance Section, Fleet-Surgeon JOHN LLOYD THOMAS of H. M. S. *Excellent*, related his experiences as medical officer of the British Relief Expedition during the siege of the legations in Pekin in 1900, dwelling chiefly upon the cases of sunstroke and the treatment found most efficacious, and upon the means adopted for purification of the drinking water supplied to the forces on the march.

**Purification of Drinking Water Obtained from Suspected Sources.**—Staff Surgeon T. FALCONER HALL discussed this question in a paper of some length. The most certain means of obtaining a pure supply of drinking water was by distillation, but this was practicable in general only when the troops were in camp or garrison, and when they were on the march some other method had to be adopted. The next best means of purifying water was by boiling, followed by filtration. In this way the larger impurities could be removed, while the smaller microorganisms and their spores would be killed by the prolonged application of heat. The toxins which might have been previously elaborated would not, however, necessarily be destroyed by this process. The chemical methods of providing a safe and potable water which had been proposed from time to time were practically of little value, if not absolutely useless. It was impossible by this means to destroy all pathogenic organisms, especially those of typhoid fever and cholera, without at the same time rendering the water unfit to drink, if not positively dangerous.

## MEDICAL SOCIETY OF NEW JERSEY.

*One Hundred and Thirty-Seventh Annual Meeting, Held in Asbury Park, N. J., June 23, 24, and 25, 1903.*

FIRST DAY—TUESDAY, JUNE 23.

THE meeting was held in the Coleman House under the presidency of Dr. E. L. B. GODFREY of Camden.

**Adoption of New Constitution and By-Laws.**—For a year past a committee has been busily engaged in revising and altering the constitution and by-laws so as to make them conform to the new plan of organization adopted by the American Medical Association and by many other State societies. The committee presented a printed report, which was adopted without discussion. This makes New Jersey the twenty-seventh State to fall in line.

**Abuse of Medical Charity.**—Dr. E. Y. SUTPHEN of Newark presented the report of this committee. He said that in the London and in the St. Bartholomew's Hospital a plan of home visitation had been adopted with some advantage. It was probable that a similar plan would be the best one for this country. The committee suggested the propriety of the State society recommending to the district medical societies, especially those embracing the larger cities, to take some practical steps to secure themselves the protection they desired. It would probably entail only a very moderate per capita expense.

This was all the committee had to suggest, and as the committee had never had more than a half-hearted support from the time of its establishment, despite the earnest work of its chairman, it was perhaps well for the peace of mind of the society that the committee had been discharged, and the uncomfortable prominence given this very awkward subject was a thing of the past.

**Progress in Medicine and Therapeutics.**—Dr. W. H. IRELAND of Camden was the author of this paper. With regard to typhoid fever the opinion was expressed that the needless use of tub baths in this disease was responsible for certain unsatisfactory results, and that the statistics would be improved if some of these cases were treated instead by sponge baths. Little if any advance had been made in the medical treatment of typhoid fever. In marked contrast was the present status of the treatment of malaria and yellow fever. Dr. Councilman had recently announced that he had discovered the specific germ of smallpox, an achievement of much interest and importance if confirmed by further investigation. The serum treatment of disease promised to become increasingly prominent in the future. Apparently the fact had been clearly demonstrated that the resistance to many diseases was decidedly increased by the addition to the blood of a person afflicted with the disease of a small quantity of blood serum from a person who had just recovered from the disease. Brief mention was made of the possibilities of treatment by animal extracts.

**Progress in Laryngology.**—Dr. B. A. WADDINGTON of Salem presented this report. For the control of epistaxis the author recommended the introduction on a probe of a long cone of loosely wound cotton wet with hydrogen peroxide. The apex of the cone should reach the posterior nares, and by placing the finger on the base of the cone at the anterior nares the probe could be readily withdrawn. Such an application caused prompt

coagulation of the blood and an enormous swelling of the blood clot, thus effectively checking the nasal hemorrhage. Referring to the relation of the uric acid diathesis to certain cases of hay-fever, the statement was made that not a few of these cases could be relieved by the internal administration of nitro-muriatic acid in doses of from three to five drops in water after meals. Its good effect was usually apparent in one or two days, but to secure the best results the remedy should be continued throughout the hay-fever season.

**Progress in Surgery.**—Dr. CHARLES YOUNG of Newark read this paper. Speaking of gall-bladder surgery he said that Cushing had found that 30 per cent. of the gallstone patients operated upon at the Johns Hopkins Hospital had previously suffered from typhoid fever, and Ochsner found that 35 per cent. of his cases had previously had acute or chronic appendicitis. This fast was interesting in connection with the theory of the etiological relation of bacterial invasion to cholelithiasis. In the diagnosis Ochsner relied rather upon digestive disturbance, gaseous distention of the abdomen, dull pain extending to the right in the epigastric region on a level with the tenth rib, and extending upward toward the right shoulder-blade, and a history of one or more attacks of typhoid fever or of appendicitis. If to this were added colic and jaundice, additional confirmation was afforded. The chances were thought to be better without operation during the acute stage. In a series of 328 operative cases reported last year by Dr. W. J. Mayo of Rochester, Minn., the mortality was 2.5 per cent. Where the cystic duct was obstructed, cholecystotomy was usually found to be sufficient. In three cases gallstones were found outside of the gall-bladder with no connection with it, although they communicated by fistulous passages with the intestine. There were thirty-four cases of cholecystitis with three deaths, thus showing the serious nature of the affection. Jaundice in connection with stones of the common duct was a very variable feature; in many cases it was so slight as not to attract attention. Mayo had had no deaths from hemorrhage after adopting Robson's suggestion of administering calcium chloride. Of the eight deaths in the benign cases four were from progressive inflammation of the liver ducts. Mr. Moynihan of Leeds, England, had contributed to the literature an instructive article on cholecystectomy. One of no less experience in this field than Kehr recommended removal of the gall-bladder as a routine measure in the treatment of cholelithiasis. The gall-bladder should never be removed unless the surgeon was convinced that the common duct was patent.

**A Case of Amœba-Coli Dysentery.**—Dr. PHILIP MARVEL of Atlantic City reported this case. He said that the lesions produced by the amœba coli were almost always present in the large bowel. The ulcerations were characteristic, there being nodular projections and small cavities filled with gelatinous pus. The most intense change appeared to be in the membranous coat. The primary action of the amœba was believed to be the formation of granulation tissue, and that when pus formed it was always the result of infection. The case reported occurred in a woman of thirty-five, a native of New Jersey. She complained of intense, deep pelvic pain without abdominal distention or diarrhœa. In a few days the stools became dysenteric. The usual treatment for this condition was tried for two or three weeks, with unsatisfactory results. During this time there was more or less uterine hemorrhage. At the first examination a mass was found in the left broad ligament, but this disappeared subsequently. It was a pyosalpinx Curettage was done for the relief of this complicating condition, and strange to say, the dysentery was checked by this operation on the uterus. An examination with the proctoscope showed a large ulcerated area about two inches above the rectum. At Dr. Marvel's request the case was subsequently placed under the observation of Dr. John Clarke of the University of Pennsylvania. The Widal reaction was negative, whereas the bacteriological examination served to identify the amœba coli. The patient discontinued treatment after a time, and although not well she was greatly improved. Three microscopical examinations were made of material removed from the local seat of the disease by swabs, but no amœba-coli organisms were found at this time.

Dr. JUDSON DALAND of Philadelphia observed that it was quite possible that there were other ulcers beyond the field of vision. The ulcers were usually superficial, thus admitting of local treatment, and at the same time explaining the rarity of perforation. He thought benefit should result from washing out the colon with a solution of quinine, in view of the known action of this remedy when in solution in the blood upon another amœba, the malarial plasmodium.

Dr. Marvel replied that he had given quinine by the mouth, but had not used it locally, because of the negative results obtained by Dr. George Dock of Michigan, with this treatment, using quinine solution in strengths of 1 to 1,000 and 1 to 500.

**President's Annual Address.—The Educational Standards of the Medical Profession of New Jersey, Past and Present.**—Dr. E. L. B. GODFREY of Camden delivered this address. He said that in the first year of the existence of the Medical Society of New Jersey, or 136 years ago, the question of medical education was taken up. Only five years later the State required that the standard of medical education should be determined and vouched for by the Supreme Court of the State. In 1816 the State transferred the licensing power to the Medical Society of New Jersey. From 1851 to 1854 a fierce fight was waged between this society and the medical colleges of the country, and in the latter year a law was passed which admitted the graduates from all recognized medical colleges in the country on depositing an English translation of the diploma. Finally, in 1866, the Medical Society of New Jersey surrendered its examining and licensing power. Medical practice remained in New Jersey almost without restriction from 1854 to 1890. Public and professional sentiment became aroused over the imperfect training given in medical schools, and the conclusion was reached that the State could not accept a diploma from a medical college outside of its jurisdiction, especially from a private teaching institution. In 1890 the State of New Jersey established a minimum standard of qualifications, and appointed examiners for those applying for license to practise medicine within its borders. These officers were appointed by the State and were directly responsible to the State. It was not at first thought to be expedient to establish a very high standard. In 1892 an act was passed requiring a course of medical education extending over three calendar years. In 1894 a law was enacted which required a competent common-school education and a course of medical training extending over four calendar years, with an examination in fourteen subjects, and a general average at the examination of 75 per cent. By a law enacted in April of the present year, and going into effect on July 4, 1903, the applicant was required to have a diploma issued after four years in a State normal or high school of the first grade in this State, or any other institution of equal grade, or a certificate of having successfuly passed the examination for the freshman class of a reputable literary college. This new law also requires attendance at a medical school upon four courses of lectures of nine months each in different years. Physicians who have been in reputable and continuous practice for five years prior to 1903 are exempted from one course of lectures, and those who have practised for ten years are exempted from two courses of lectures. The examination papers of candidates are to be filed in Trenton and are subject to public inspection. The speaker said

that by a recent judicial decision it had been decided that osteopathy was illegal in New Jersey—indeed, that no system, medical or religious, such as the laying on of hands and Christian Science, was legal unless proved to be in conformity with the standards of the State. At the present time there was about one physician in New Jersey to every 800 of the inhabitants. The enforcement of the medical law in the State rested with the local prosecutors, and the Medical Society of New Jersey could do much in the way of co-operating with such prosecutors.

The speaker then discussed at great length the question of interstate reciprocity in the matter of medical licenses, and came to the conclusion that this was impracticable, and must be so for many years, or until the laws of different States became uniform, because there was no common ground for united action. Because of the two powerful adjoining States, New Jersey must be especially careful about indorsing diplomas from those States. Laxity in this respect would be a poor State policy, and would inevitably rob the medical profession of that State of much of its summer practice. The licenses of other States were not indorsed until all of the requirements of New Jersey, moral, academic, and medical, were complied with.

**Presentation of a Gavel.**—Dr. DANIEL STROCK of Camden, on behalf of the attending staff of the Cooper Hospital at Camden, presented to their colleague, Dr. E. L. B. Godfrey, the President of the State Society, a gavel made from some of the wood of the hospital.

**Osteopathy.**—Dr. DANIEL STROCK made a brief address in which he made clear, so far as the nature of the subject would permit, what was really embraced in the term osteopathy. He called attention to the fact that Dr. Still claimed to have invented osteopathy in 1874, and that although one would naturally infer that the term was applicable only to the osseous system, it was used to express mechanical treatment invoked to cure disease dependent upon disturbed relations not only of the bones, but of the ligaments, tendons, nerves, and blood-vessels.

Dr. R. C. NEWTON of Montclair followed with a paper, in which he showed that Dr. Still was not the originator of this system, and that his so-called discovery had been antedated by an Italian woman, who was brought to this country by General Woodford and who was known to have practiced osteopathy here. He added that there was a germ of truth in osteopathy, as some of the benefit was due to active and violent manipulation which regular practitioners advised merely, but which the osteopaths actually executed, and thus made sure that their advice was followed.

SECOND DAY—WEDNESDAY, JUNE 24.

**Progress in Bacteriology.**—Dr. R. B. FITZ RANDOLPH of Trenton read this paper. He said that since the publication of Koch's dictum regarding the non-communicability of bovine tuberculosis to man many investigators had diercted their attention to the subject, with the result that there had been accumulated considerable evidence to show that bovine tuberculosis was communicated to human beings either through wounds or by means of food. Cows secreting tuberculous milk might be so slightly infected with this disease as not to lead to the diagnosis of bovine tuberculosis without resort to the tuberculin test. It had been shown that the tubercle bacillus could thrive on the surface of fruit, and could be so communicated from man to man, but it was improbable that this often occurred outside of the laboratory because of the comparatively narrow limits of temperature within which the tubercle bacillus would grow. According to Trudeau, the presence of a living germ was necessary to secure the development of immunity. The production of a tuberculous antitoxin had not met with much success, the nearest approach being the serum bearing the name of Maragliano.

**Typhoid.**—There was little to record concerning the bacteriology of typhoid fever except with regard to the use of sera. Apparently a very good degree of immunity could be conferred by the process of so-called vaccination, but the period of immunity was uncertain. The difficulty in preparing an active curative serum was that the toxin was locked up in the cell. The serum diagnosis of typhoid fever was now so thoroughly established that it was employed in all laboratories. The His method of isolating the typhoid bacilli from the fæces was not frequently employed because of certain practical difficulties. Many of the sources of typhoid fever were still shrouded in mystery. While water-borne typhoid was very common, there were many other sources of infection fully as important. The transmission of the disease by flies, and presumably by other insects, was now well established. Welch had recently made the statement that the majority of cases of infection arose from the communication of the disease from one typhoid-fever patient to another, or through the medium of infected articles. Paratyphoid bacilli had been first described in 1896. These bacilli produced an acid reaction in milk, and resembled the colon bacillus in many respects, but did not produce indol. These organisms had been occasionally recovered from the fæces and urine. The mortality from paratyphoid infection was usually very low, being practically *nil* with the variety of this bacillus designated as "A."

**Plague.**—The persistence of the plague in San Francisco for the past three years was probably largely attributable to the unwarrantable action of the health authorities there. A relatively small number of the bacilli might cause the disease. As in typhoid fever, two methods of treatment had been proposed, *i. e.* protective inoculation and the use of a curative serum. Good results had followed the use of Haffkine's protective inoculations, but the reports concerning the curative serum were so far contradictory. The consensus of opinion seemed to be that in mild cases it was of decided value, and not of much use in severe cases.

**Dysentery.**—Reference was made to the discovery by Shiga of the bacillus of dysentery, and to the results obtained by Duval and Darrett in isolating this bacillus from forty-two cases of infantile summer diarrhœa. The researches to be carried on this summer would probably very greatly add to our knowledge of this disease.

**Report of Committee on Legislation.**—Dr. L. M. HALSEY of Williamstown presented this report. It stated that at the last annual meeting of the State society the committee had been instructed to endeavor to secure legislation for the protection of the physician on the witness stand. A bill had been drafted and presented to the Legislature by the member from Gloucester. Considerable opposition developed, the lawyers claiming that it would make it practically impossible for them to secure evidence in divorce cases. It was thought that the work accomplished by the commmittee would prove a useful entering wedge in the future. The committee had also worked energetically to defeat the osteopathy bill, and it had been insisted that the State could not discriminate between various so-called systems of healing, and that all practitioners of the healing art should be treated alike. Several other members of the State society and a number of homœopathists assisted in opposing the bill. It was not reported out of committee, but there was reason to believe that a similar effort would be made again before long. The committee also assisted in raising the standard of medical education for the State, which placed it practically on a level with the standard of the State of New York. The committee felt that its work was of such importance that the committee should be enlarged by the addition of representatives from each district society, and that the committee should be instructed to endeavor to secure the adoption of a standard for fees in connection with lunacy examinations, post-mortem examinations, and coroner's inquests. The present committee felt that

the minimum fee for a lunacy examination in the case of an indigent lunatic should be $5, the fee for post-mortem examination from $25 to $100, and the fee for services in connection with a coroner's examination from $5 to $10, depending upon whether or not it was held in the same county as that in which the physician resided.

**The Organization and Operation of Hospitals and Other Charitable Institutions in the State of New Jersey.**—Dr. WALTER B. JOHNSON of Paterson, the third vice-president, presented this essay. He said that male boards were business-like and raised more money, and likewise spent more freely for hospital maintenance than female boards, but they were apt to be too much engrossed in their own business. The female managing boards were most careful about the finances. Some experienced hospital workers favored a mixed board. The writer unhesitatingly recommended what was called the departmental system of management.

**Progress in Ophthalmology.**—Dr. TALBOT R. CHAMBERS of Jersey City presented this report. He said that during the past year there had been a marked increase in trachoma and conjunctivitis in Jersey City and in other parts of the country. In Russia the inspectors found not less than 5 per cent. of the children of the schools suffering from trachoma, and in many of the country districts nearly 50 per cent. of the school children were so afflicted, and this, too, despite the fact that the government expended annually $87,500 in the effort to control this disease. Attention was called to the importance of prompt treatment of all cases of penetrating wounds of the eye, and to the value of the eye magnet, and sometimes of the *x*-ray, in connection with cases of this kind in which a particle of iron or steel had passed into the eye. The subject of determining the conditions of the eyes of school children was next considered, and a system was described which was thought to be applicable to the public schools. It was intended to introduce it shortly into the schools of Jersey City.

**Operation for Complete Epispadias by Transplantation of the Urethra.**—Dr. FRANK C. CANTWELL of Trenton was the author of this paper. He described the technique of the operation, and reported his own two successful cases and others successfully performed by others. It was claimed for the operation that it left the penis not only normal in appearance but in the structure and relations of the parts. One of these patients had recently become the father of a healthy child.

**Infantile Colic.**—Dr. ALEXANDER MCALISTER of Camden presented this paper. He said that the most trifling circumstance in the life of the mother was often sufficient to give rise to colic in her infant. An improper rubber nipple was a fertile cause of colic. The best of such nipples after having been used for a short time permitted too free flow of milk, and it was a stubborn fact that a child having once become accustomed to such a nipple would persistently refuse to return to sucking at the breast. It should be made the rule to discard a rubber nipple after having been in use two weeks. The nipple therefore should be new, the perforation very small, and the bottle should be held by an attendant while the infant was feeding. The greatest care should be taken not to resort to narcotics until every other means had been faithfully tried and the nature of the colic carefully determined. It should be borne in mind that the dose of one drop of paregoric was the sure forerunner of ten drops of that delusive nursery medicine. A great deal could be accomplished in the relief of colic by friction and warmth, the latter being most conveniently applied by means of a small hot-water bag. A useful carminative, when one was indicated, was the formula for paregoric with the opium left out. According to Rotch, alkalies should also be administered. Milk of asafetida often proved exceedingly useful as a remedy for the relief of infantile colic.

Dr. WILLIAM E. DARNALL of Atlantic City said that some observers had noted that an attack of pain in the nursing mother might give rise to colic in her infant. This had long ago been pointed out by Dewees, who had observed a persistent colic in an infant coincident with a severe toothache in the mother and disappearing when that was relieved by extraction of the bad tooth. The influence of cold, as from lying in a wet diaper, should not be forgotten. According to Dr. Illoway of New York the play of the infant's features was an aid to the correct diagnosis. Thus where the colic was only a symptom of a more serious disorder it would be found that the child did not draw up its limbs against the abdomen as in ordinary simple colic.

Dr. JOHN C. JOHNSON of Blairstown remarked that a small umbilical hernia was a not infrequent cause of infantile colic.

**Mosquitos and Malaria.**—Dr. J. J. KINYOUN of Glenolden, Pa., presented this paper. He reviewed the work of Ross and others and pointed out the differences between the eggs of the culex and of the anopheles mosquito. The eggs of the former were deposited in one adherent mass, while the latter were deposited separately and were provided with air cells which enabled them to float. Of the sixty-one varieties of anopheles it had been found that only four or five in this country were responsible for the dissemination of malaria. The period of incubation for the tertian form was from five to fifteen days; that of the æstivo-autumnal and of the malignant tertian was five days, while that of the quartan had not yet been determined. The speaker said that he did not personally indorse the opinion of immunity from malaria. Many children did not appear to show any serious consequences from malarial infection, although an examination of their blood would show many malarial organisms therein. In 1890 he had had the good fortune to observe six cases of mixed infection of typhoid and malarial fever. In considering prophylaxis it should be remembered that the mere fact of the prevalence of anopheles did not necessarily mean malaria. It had been observed that in certain districts largely given up to the cultivation of tomatoes the people were wholly free from malaria; also that when the anopheles was fed upon tomatoes, melons, and other substances containing fruit acids these mosquitos could not be made the means of carrying malarial infection.

Dr. JUDSON DALAND of Philadelphia said that while he was convinced that the mosquito was the most important agent in the transmission of malaria, he believed it was not the only one. He believed that the existence of a special form of the malarial plasmodium explained the malignant malarias found about the Black Sea and in the tropics. It was said that in the southern part of Russia malaria and typhoid fever present such a similar clinical picture that the differential diagnosis is hardly possible without a microscopical examination of the blood. He had seen a double infection with malaria and typhoid in the soldiers returning from Cuba. It was perfectly conceivable that when a typhoid infection occurred the resulting changes in the blood interfered with the usual development of the malarial parasite. The reader of the paper had touched upon the interesting question of latency and immunity. It was undoubtedly true that the blood of many blacks living on the African coast showed the presence of the malarial parasite, unassociated with symptoms of malaria, but if these persons left this region and ascended the mountains the usual phenomena of this disease became apparent. The disease was really latent, and these persons were not really immune. Not only should the anopheles mosquitos be destroyed as a prophylactic measure, but persons ill with malaria should be protected from mosquitos, because if the latter had access to such persons they would convey the disease to others.

Dr. B. D. EVANS said that he had been assured that in "the black belt" of Alabama, where the most malig-

nant forms of malaria were rife, no mosquitos were found—an interesting but to him a very puzzling fact.

Dr. C. P. Noble of Philadelphia said that in early life he had lived in a low-lying part of the country which was at the time very malarious. At present there was practically no malaria there and this the physicians of the locality attributed to the fact that the old-fashioned wells had been superseded by driven wells.

Dr. Marcy spoke of the commercial aspect of the movement for the destruction of mosquitos, and remarked that as this alone would mean the redemption of large tracts of valuable land, it was worthy of serious consideration wholly apart from its sanitary features. The mosquito was undoubtedly an intermediary host, but it was just as certain that there were other methods of propagating malaria. A short time ago he had observed that almost every patient in the military hospital near the Black Sea was suffering from a severe form of malaria, yet mosquitos were not prevalent, from which he inferred either that the mosquitos in that region were very much overworked or else there was some other means of transmitting malaria.

Dr. Kinyoun, in closing the discussion, said that malignant malarial fevers occurred not only in Alabama but along the Atlantic coast from the Dismal Swamp to Galveston, Texas, and throughout this region the anopheles mosquito had been found. He was disposed to believe that there was another kind of mosquito or other insect that was capable of transmitting the infection, particularly in those disputed forms of which "black water fever" might be taken as the type. He also believed that Cuban malaria so-called was due to a type of parasite not yet described.

**Alexander Operation in the Treatment of Retrodisplacements of the Uterus.**—Dr. Frank M. Donahue of New Brunswick was the author of this paper. He stated that the one essential for a successful Alexander operat on was that the uterus should be freely movable and the tubes and ovaries healthy. Several modifications of the operation had been performed, but they presented in common the disadvantage that the abdominal cavity must be opened. Anterior fixation was objectionable not only because of probable complications in women of child-bearing age, but because the operation increased the tendency to congestion which in turn led to endometritis. Of forty cases in which the author had done the Alexander operation thirty had been heard from and all had been symptomatically cured. About 20 per cent. had since been delivered of full-term children. The operation was capable of effecting a cure in properly selected and otherwise very troublesome cases and without any mortality.

**Retrodisplacements and Their Treatment.**—Dr. J. M. Baldy of Philadelphia presented this paper. He said that retrodisplacements were almost always associated with other diseases, and the symptoms presented were usually those of such associated disease. A retrodisplacement of the uterus, even with prolapse of the ovaries, might exist for years without any symptoms. In such cases marriage was apt to lead in a short time to symptoms referable to the ovaries. The treatment of retrodisplacement was therefore the treatment of conditions in which the retrodisplacement was only an incident, and a treatment which wholly ignored the retrodisplacement might be completely successful. The operation which he advised was one in which the round ligaments were seized, drawn back into a loop behind, and fastened with a stitch. The utility of pessaries was so limited that he would not discuss them. Where they did good a tampon would act equally well. The speaker said that the majority of women who came to him with a pessary in the vagina had no malposition of the uterus or any pelvic disease and the indications were that there never had been. These women were neurasthenics or dyspeptics.

Dr. Mortimer Lampson of Jersey City expressed the opinion that the Alexander operation was essentially wrong in its conception, and was based on wrong anatomical principles. His personal experience, together with observations of the operation as done by others, had impressed him with the great difficulties of this operation, and with the fact that Kelly's modification was an improvement on the original Alexander operation.

Dr. Emery Marvel of Atlantic City said that there were several objections to the Alexander operation. Not the least of these was the fact that the surgeon worked largely in the dark and was liable to overlook complications, such as tubal and ovarian disease. The objection made to the other operations that the peritoneal cavity must be opened did not seem to him to carry much weight, and another objection, the liability to hernia, fell to the ground, for the Alexander operation presented two possibilities of the development of hernia as against the one chance of such a sequela after laparotomy. Ventral suspension was an operation that had done much good, but a serious objection to it was the liability to dystocia. He objected to Dr. Baldy's operation on the ground that it weakened the original supports of the uterus.

Dr. Philander A. Harris of Paterson heartily commended the position taken by Dr. Baldy, but said that he had had no personal experience with Dr. Baldy's operation. He believed that pessaries were occasionally useful in retrodisplacements of the uterus unassociated with other pathological conditions.

Dr. C. P. Noble was of the opinion that there were many cases of uncomplicated retroversion that gave rise to symptoms, and that many of these cases soon became complicated by prolapse of the ovaries. He had found no difficulty in curing the uncomplicated cases by the Alexander operation, an operation that he had done over 200 times. He had never known a hernia to follow this operation when it had been properly done—*i. e.* when it had been finished as a Bassini operation. It had not been his experience that in doing the Alexander operation one was liable to overlook disease of the adnexa, and where such disease was present he preferred to remove the uterus.

Dr. E. J. Ill of Newark was positive that the very extreme opinions held by Dr. Baldy were erroneous. Dr. Baldy characterized the Alexander operation as a foolish procedure, while admitting that he had only done it a few times. Dr. Baldy's operation involved the suspension of the uterus by its weakest point, and the suspension was effected in such a way as to give the least amount of leverage. It was far from true that pessaries were things of the past; he believed that nine-tenths of his hearers who were working in this field and were not operators, were using pessaries with great benefit to their patients. Although an operating surgeon himself, he was free to say that it was not at all necessary to operate in all of these cases.

Dr. Baldy said with reference to the liability to hernia after the Alexander operation, that certain authorities in New York had placed on record between forty and sixty cases of hernia having this origin.

**Pneumonia Simulating Appendicitis.**—Dr. J. P. Crozer Griffith of Philadelphia read this paper. He said that the fact that pneumonia in childhood might simulate appendicitis had been long known, but had been largely overlooked. The first he had seen was in a hospital, and he had been asked to see the case on the supposition that the child was suffering from arsenical poisoning, induced by large medicinal doses of arsenic. There were evidences of peritonitis, but as a routine measure the lungs were examined and a right-sided penumonia thereby discovered. The next day the evidences of peritonitis had disappeared. Another case had been

sent into the hospital with a diagnosis of appendicitis. There was no cough, and the signs and symptoms pointed to abdominal disorder. In a day or two pneumonia was discovered, and in time the abdominal symptoms disappeared. Attention was called to the fact that in these cases the high temperature and the rapidity of respiration should have shown the attending physicians sooner the possibility of the existence of a pneumonia. In another case coming to the hospital there was a history of a typical attack of appendicitis, which had been recovered from and had been followed by a relapse. On admission the temperature was 103° F., and the abdomen was tender and tympanitic. The case was found to be one of pneumonia, and the physician who had attended the child, although at first very indignant, examined the little one, and then admitted the correctness of this diagnosis. Several other cases were also reported. There had not been many cases recorded in recent literature. One of the most interesting articles on this subject had been written by Dr. Maurice Richardson of Boston. It was evident that in early life there was a tendency for the patient to refer the pain of pneumonia or of pleurisy to the abdomen. This was more apt to occur when the thoracic trouble was situated low down and when the right side was affected. Along with the abdominal pain there were constipation and abdominal tenderness. Due consideration must be given to the occurrence of a sudden rise of temperature to about 103° F., the tendency to maintain this temperature, the rapidity of respiration, the diminution or disappearance of tenderness on deep pressure with the flat of the hand. No operation for appendicitis should ever be performed in children until after careful and repeated examination of the lungs.

**Some Practical Methods of Hydrotherapy for General Practice.**—Dr. ELIOT GORTON of Fair Oaks, Summit, presented this paper. He said that a correct technique and attention to detail were necessary to secure good results from hydrotherapy. The essentials of such treatment were water, a bath tub, a bath thermometer, and a proper technique.

**Warm Full Bath.**—This bath should have a temperature between 98° and 102° F., and there should be complete immersion except the head, the latter being first wet with cold water, and then wrapped up with a moist towel. This was an essential point in the technique, although often overlooked. The bath should last for fifteen or twenty minutes. It had a marked sedative action, and was very useful in cases of delirium and insomnia. On leaving the bath perspiration should be abundant. Herein lay the great value of this bath in disease of the kidney. For a person suffering from heart disease the temperature should never exceed 95° F.

**Half Bath.**—The head should be wrapped in a towel wet with cold water, a warm drink should be given, and the patient should be seated in water at 90° F., while an attendant throws cold water with some force against the back and upper extremities, and employs frictions for a minute or two. The procedure should then be repeated on the front of the chest after one minute. The temperature of the water should be gradually reduced from day to day, but should never be lower than 68° F. In the aged the first temperature of the bath should be 95° F. In tuberculosis this bath was exceedingly useful. The temperature should be between 85° and 80° F., and the bath should last for six minutes. Such baths caused a lessening of the distressing cough, an increased appetite, and a wonderful gain in body weight. The bath was also very useful in cases of epilepsy, whether or not bromides were being given.

**Wet Packs.**—In maniacal conditions the effect of a prolonged wet pack was very marked. The temperature of the cold pack should be from 70° to 60° F., and of the high pack, 100°. Three woolen blankets are placed upon the bed and a coarse linen sheet, wrung out of water at the desired temperature, is placed over the blanket. The patient is then placed upon the sheet, and the latter is brought around the body and the arms and shoulders enveloped. The sheet should be tucked in closely between the limbs, so that it comes in contact with every part of the body and carefully excludes the air. When properly applied there is no discomfort after the first shaking. The duration of the pack should never be less than half an hour, and might be continued for two hours. While in the pack the patient should never be left alone.

**Drip Sheet.**—The only difference between the drip sheet and the wet pack was that the former was not wrung out, and the attendant applied rapid friction through the sheet. During the process, water at a slightly lower temperature might be poured upon the patient.

**Some Diseases of the Eye Due to Nasal Infection.**—Dr. S. ZIEGLER of Philadelphia was the author of this paper. The opinion was expressed that corneal ulceration arose chiefly from nasal infection. It was pointed out how infectious disease of the antrum of Highmore might lead to a pouring out of an infectious discharge into the nose and the carrying of the same through the lacrymonasal duct into the ocular chamber. The constitutional element should not be overlooked. Nasal obstruction and mouth-breathing were important predisposing factors. Over-indulgence in coffee, tea, and sweets gave rise to a constitutional condition which was exceedingly prone to lead to corneal ulceration. Irrigation of the nasal chambers was an important part of the treatment of corneal ulceration. For this purpose he made use of a 1-to-4 solution of peroxide of hydrogen, and sometimes also of cocaine or similar substances for reducing the nasal engorgement. A patulous tear duct must be secured, preferably by rapid dilatation without incision. A repetition of this procedure was rarely required.

Dr. W. P. EAGLETON of Newark said that it long had been known that about 90 per cent. of corneal ulcers were associated with nasal lesions, but it had not yet been shown that these ulcers were dependent upon the nasal lesions. The advisability of treating the duct would depend upon whether or not it was closed. To determine whether or not the duct was patulous, a drop of fluoricine should be applied to the conjunctival sac and the patient told after two or three minutes to blow the nose. If the duct were pervious some of the nasal secretion would be stained. He had seen very severe lacrymal abscesses follow dilatation of the nasal duct.

Dr. T. R. CHAMBERS of Jersey City said that there were thousands of cases of corneal ulcer that were independent of nasal lesions. He had frequently found the process of dilatation of only temporary benefit, necessitating ultimately resort to incision.

**Two Cases of Transient Complete Blindness of Both Eyes.**—Dr. C. J. KIPP of Newark reported these cases. —The first was one of amaurosis, arising probably from auto-infection. It lasted thirty-six hours and terminated in recovery. The second case was one of idiopathic optic neuritis of three weeks' duration, in which recovery also occurred.

THIRD DAY—THURSDAY, JUNE 25.

**Acute Inflammation of the Accessory Sinuses of the Nose.**—Dr. N. L. WILSON of Elizabeth read this paper. He said that anything which hindered free drainage from the upper part of the nasal cavity predisposed to such inflammation and to suppuration of the accessory sinuses. Pneumonia, influenza, scarlet fever, measles, typhoid fever, diphtheria, smallpox, cerebrospinal meningitis, and erysipelas were the diseases likely to lead to such affections of the sinuses. The inflammation might reach the sinuses from direct extension of the inflammation or through the blood stream by general systemic infection. The latter was much less frequent. The diseases most frequently giving rise to this order were

epidemic influenza and croupous pneumonia. Some writers believed that polypi were occasionally the cause of suppuration, but he was disposed to think that the polypi were the result rather than the cause of this suppuration. Another cause was irritation by dust-laden air, a fact which probably explained the frequency with which automobilists were affected with inflammation of the accessory sinuses. In acute inflammation the mucosa became congested and infiltrated with round cells, and an acute catarrh of the membrane developed. The exudation might become seropurulent or purulent. If the sinuses became blocked the exudation was retained under pressure and gave rise to symptoms. In every case of acute coryza of the exanthemata one should bear in mind the possibility of infection of the accessory sinuses, and remember that the antrum of Highmore, the frontal sinusus and the anterior ethmoidal cells communicated with the nasal chamber. Inflammation of the sinuses was usually ushered in by a general malaise similar to that experienced in ordinary grip. There was apt to be more or less stiffness of the muscles of the neck. Tenderness over the cheek or forehead might be elicited on slight pressure. The discharge was sometimes a straw-colored fluid, sometimes blood-stained, sometimes mucopurulent or purulent. The alternation in character of the symptoms was very suggestive of sinusitis. If the middle turbinate were contracted by adrenalin there would probably be found some discharge from the middle meatus. Transillumination was not infallible, although valuable in many cases. The clouding observed at such an examination was not due to the pus but to the thickened tissue. It was interesting to note that this valuable method of examination was not given to us by foreign investigators but by a physician of Philadelphia, who brought it forward in 1885. One of the most important steps in the treatment was to order the patient to bed and insist upon absolute quiet. This should be followed by diaphoresis, excited by a hot bath and hot drinks. The application of hot cloths to the head and the administration of calomel were useful adjuvants. After the skin and bowels became active the ice-bag might be substituted for the hot cloths, and the well-known tablet called "rhinitis" administered. Belladonna seemed to have a selective action on these parts, and by its use it was often possible to abort a coryza. A warm spray of Dobell's solution and the application of adrenalin were valuable local measures. The use of cocaine was not advisable because of the subsequent reaction. When suppuration was present cocaine and adrenalin should be used to facilitate the introduction of the catheter. Sometimes it became necessary to plunge a trocar through the antrum under the inferior turbinate, and force a cleansing fluid in until it escaped from beneath the middle turbinate. A few washings would usually suffice. The bleeding resulting from a turbinotomy was of decided value in lessening the congestion of the parts. While not a few of these cases would recover without treatment, the physician was not excused from doing what he could to facilitate this.

Dr. T. W. Corwin of Newark, speaking of the diagnosis, recommended that the body of the patient be bent over the back of a chair, so that the vertex pointed almost directly downward. The patient was then directed to blow the nose forcibly two or three times, when, on reassuming the upright position, it would often be possible to observe an accumulation in the attic of the nose, thus showing that the sinus had been emptied while in the inverted position. In the treatment he had obtained good results from projecting a current of hot dry air into the nose.

Dr. George E. Reading of Woodbury said that while belladonna was useful in these cases, its unpleasant effects could be largely prevented and its beneficial action augmented by the addition of aconite.

**A Clinical Contribution to the Knowledge of Tubercular Disease of the Female Urinary Tract.**—Dr. Edward J. Ill of Newark presented this paper, which was based on a study extending over the past thirteen years. The diagnosis, he said, could not be considered until the tubercle bacillus had been found, yet this was not always easy. The origin of such tuberculous inflammation was most frequently in the pelvis of the kidney. Cases were presented to show that not only the bladder but the ureter might apparently recover spontaneously. He did not, however, wish to be understood as advising that an infected ureter should be left undisturbed. The most frequent symptoms were pain in the loin and iliac region of the affected side, followed by pain in the bladder. Pain on urination always meant infection of the bladder, the most frequent sites being the trigone and the neck of the organ. Hæmaturia should always be looked upon with suspicion. It most frequently pointed to stone or malignancy, but the fact that it might be dependent upon tuberculosis should not be lost sight of. Every case of pus in the urine should be examined for tubercle bacilli when other obvious causes were absent. The prognosis of tuberculous disease of the urinary tract was usually considered to be bad, nevertheless there were patients who recovered and remained well for years. In making the bacteriological examination for diagnosis, one should be careful to exclude contaminations, particularly with the smegma bacillus, by using a specimen of urine obtained by means of the catheter under strict aseptic precautions.

**Court Testimony of Medical Experts in Mental Diseases.**—Dr. B. D. Evans of Morris Plains read this paper.

He said that New Jersey courts still held that if the prisoner knew the difference between right and wrong of the act committed he was criminally responsible in the sight of the law. If this were to continue to be the ruling, then progress was out of the question. It seemed to be necessary to find a precedent, no matter how moss-grown the same might be. Thus, the decisions of the noted jurist, Sir Matthew Hale, who lived in 1676, were still cited in court, yet this gentleman held to many gross superstitions, among others witchcraft. The speaker claimed that the courts could best subserve the ends of justice by making application of the law to the truths of medicine as they existed at the present time, instead of trying to make use of the medical beliefs of centuries gone by. Those who claimed to be experts in several branches of medicine might reasonably be looked upon with suspicion. The medical and legal professions should endeavor to establish a standard for medical experts, and those essaying to be such should be required to qualify in accordance with such standard, and the fact be made a part of the records of the county. He suggested that counsel on each side should each select one expert, and the judge a third, and that the evidence should then be summed up, and submitted to the court. This would eliminate the objection that these experts were paid advocates. The expert should remember that dogmatic evidence did not favorably impress either judge or jury, and they should carefully abstain from even the appearance of assuming the rôle of advocate. He should not hesitate to confess his ignorance, for even an expert could not reasonably be expected to be a medical encyclopedia. To be drawn into petty arguments was always unwise, even should the court be patient enough to allow it.

**Unusual Malformations in the Female Generative Organs.**—Dr. Emery Marvel of Atlantic City presented this paper, together with specimens and colored plates.

**Vaccination.**—Dr. George E. Reading of Woodbury discussed this subject. He said that, as a general rule, the immunity conferred by vaccination was not so long in young children as in adults, but in the vast majority of cases a successful vaccination in childhood, and again in adolescence, would give protection for life. The present school laws were not sufficiently stringent to secure

proper vaccination of young children, as shown by the fact that in a recent school census it was found that 70 per cent. of the children had never been vaccinated. Of course, it was the part of wisdom to revaccinate when there had been a direct exposure to smallpox. The existence of smallpox to-day was a blot upon our civilization.

Dr. W. U. SELOVER of Rahway advocated the vaccination of strong, healthy individuals as early as the sixth month, and a delay of several months in the case of delicate infants in the absence of smallpox in the vicinity. Some physicians, he said, preferred to use humanized vaccine virus for delicate infants, on the ground that the reaction was less than from bovine virus. In order that a vaccination could be considered successful it must have passed through the well-known stages without material modification. The period of protection from a primary vaccination varied from a few years to a life time, but he believed that in a few cases the protecting influence of a primary vaccination could be exhausted in eight or ten years. Certain diseases jeopardized the immunity afforded by vaccination. It was incomprehensible to him how any intelligent person could decry the efficacy of vaccination, for its efficacy could be conclusively demonstrated to any one who would place reasonable reliance on statistics. Permanently bad results from vaccination were so extremely rare as to sink into utter insignificance.

**Deformity and Its Prevention.**—Dr. T. BOWDEN of Paterson read a paper on this subject, in which he showed the need for early orthopedic treatment in such cases, and the responsibility of the family physician.

**Extensive Fracture of the Skull.**—Dr. JOHN C. MCCOY of Paterson reported this case, and presented the specimen. The outcome of this interesting case apparently sustained the author's position that it was justifiable to operate for epilepsy in every case in which the disease could be directly traced to a recent trauma. Although, he said, it was often impossible to eradicate all the pathological lesions, such operations usually caused a decided diminution in the frequency and severity of the convulsions, even though a cure were not effected.

**Officers and Place of Meeting.**—The following officers were elected: *President*, Dr. Henry Mitchell of Asbury Park; *First Vice-President*, Dr. A. W. Taylor of Beverly; *Second Vice-President*, Dr. Walter B. Johnson of Paterson; *Third Vice-President*, Dr. Henry W. Elmer of Bridgeton; *Corresponding Secretary*, Dr. Henry E. W. Hedges of Plainfield; *Recording Secretary*, Dr. William J. Chandler of South Orange; *Treasurer*, Dr. Archibald Mercer of Newark.

The society will hold its next annual meeting in Atlantic City, on June 21, 22, and 23, 1904.

---

**Landmark for the Facial Nerve.**—It is familiar to all that the facial nerve is imbedded to a certain extent in the lowest part of the innermost section of the posterior wall of the external auditory meatus, and it would therefor seem natural to suppose that the descending portion of the aqueduct of Fallopius ran downward and outward with a considerable amount of obliquity. This is, however, more apparent than real, and, in fact, the direction is almost vertical. The apparent obliquity depends upon the position of the plane of the tympanic ring, which, of course, lies much deeper at its lower than at its upper part. Hugh Jones points out that the part of the auditory canal in which the facial nerve is imbedded is the highest part of the floor of the meatus and below a line running from this upward and inward at right angles to the plane of the tympanic ring. We may therefore chisel away with confidence all the posterior osseous wall lying external and superior to this line.—*Journal of Laryngology.*

### SOME COMPARATIVE EXAMINATIONS OF BREAST MILK AND COW'S MILK AND THE EFFECT OF THE ADDITION OF ALKALIES AND OTHER ANTACIDS TO COW'S MILK.

BY CHARLES GILMORE KERLEY, M.D.,

ATTENDING PHYSICIAN, NEW YORK INFANT ASYLUM; ASSISTANT ATTENDING PHYSICIAN, BABIES' HOSPITAL.

AND

ALBERT H. GIESCHEN, PH.G., M.D.,

AND

GEORGE T. MYERS, M.D.,

RESIDENT PHYSICIANS, NEW YORK INFANT ASYLUM.

FOR many years it has been taught that breast milk is alkaline, while cow's milk is acid, and that in a scheme of scientific modification of cow's milk for infant feeding, this difference should be adjusted by the addition of some substance that would overcome the acidity of cow's milk. For this purpose the addition of lime water or bicarbonate of sodium has been generally advocated and carbonate of potassium has also been used.

One ounce of lime water or twenty to forty grains of bicarbonate of sodium (1 to 2 grs. to the ounce) has been recommended as the proper quantity to add to twenty ounces of food or milk. One ounce of lime water contains approximately five-eighths of a grain of calcium hydrate, which has nothing like the antacid value of forty grains of bicarbonate of sodium.

The most recent teaching has been that these additions have no other effect on cow's milk than to cause it to turn red litmus paper blue, and thus correspond with breast milk. To us this explanation of the benefits derived from the addition of alkalies and antacids to cow's milk in infant feeding was not satisfactory. There naturally arise the questions, what causes the difference in reaction to litmus of breast milk and cow's milk? A great many substances that are not antacids are known which will turn red litmus blue. How do we know that we are adding the proper substances to cow's milk, and if these additions have no other value or use than to turn red litmus paper blue why should they be made?

To answer these questions a series of examinations of breast milk and cow's milk were made at the New York Infant Asylum.

As the result of these examinations it was found that variations in litmus paper will lead to gross errors in estimating alkalinity of milk, and that little dependence should be placed on this test. Some other facts were also established that throw light on the effect of many routine measures employed in infant feeding, and also demonstrated that the present doctrine as to the alkalinity of breast milk and the acidity of cow's milk will have to be revised, for not a single specimen of breast milk required less than 8 per cent. of lime water to render it alkaline, phenolphthalein being used as an indicator, while many specimens required over 20 per cent. of lime water to render them alkaline. Cow's milk required from 45 to 95 per cent. of lime water to render it alkaline. We were surprised by the discovery that certified milk and "laboratory" milk required more lime water to render them alkaline than "grocery milk" bought at four and five cents a quart. The weather was cold during the time these examinations were made, so there was little opportunity for the milk to become acid from the growth of lactic bacteria, and there could be little temptation to add preservatives, which sometimes contain alkalies, and which would, therefore, reduce the quantity of lime water needed. Some of the cheap milk was obtained where the possibility of addition of preservatives was hardly probable.

Another point brought out was that lime water and a sodium hydrate solution of exactly the same strength as the lime water do not show the same results in testing for acidity; much more lime water being required than sodium hydrate solution to render the milk alkaline. This was markedly the case with cow's milk, but not so much so with breast milk. The cow's milk swelled up and became mucilaginous on the addition of sodium hydrate or lime water—much more with the lime water than with the sodium hydrate. It was further learned that the thickening of the milk was proportional to the quantity of lime water needed to render it alkaline, those milks which received the most lime water becoming the thickest. Boiling the milk and lime water did not affect the mucilaginous property, unless an excess of lime water was added, when the milk curdled.

As Hammersten states that mucin has a weak acid reaction and forms neutral mucilaginous solutions with alkalies which do not coagulate on boiling, it was concluded that part of the acidity of fresh milk is due to the presence of mucin. Bicarbonate of sodium added to fresh milk does not cause the mucin to swell and become mucilaginous, and the subsequent addition of a strong acid—lactic or hydrochloric—causes an effervescence which shows that the bicarbonate of sodium has not acted as an antacid in the milk, but has remained unchanged. Further investigation showed that the effect of adding lime water or bicarbonate of sodium to milk was to retard or inhibit the formation of curds by rennet. It was found that other salts, such as carbonate of potassium, borax, and phosphate of sodium also retarded or inhibited the formation of curds with rennet, and in this respect had the same effect as lime water or bicarbonate of sodium.

As these facts are so contrary to the generally accepted beliefs, detailed accounts of the work and the principles involved will be given.

Indicators.—A one-per-cent. solution of phenolphthalein in 50 per cent. alcohol, and red, neutral, and blue litmus paper in strips, were used. A drop of the phenolphthalein solution produced a red color with lime water, which was diluted 300 times with distilled water. The red litmus paper showed a faintly alkaline reaction with lime water which was diluted twenty times. The phenolphthalein was thus at least fifteen times as sensitive as the red litmus paper.

Lime Water.—Lime was slaked and stirred several times with water; after the undissolved lime had settled, the lime water was poured off. This

process was repeated several times to remove any potassium or sodium or other soluble matter that might be present in the lime. Distilled water was then poured on the washed lime. In all these tests lime water of the same strength was used as there was always some solid lime at the bottom of the jar, and the jar was kept in a room the temperature of which was quite uniform.

Sodium Hydrate Solution.—As lime water is almost exactly one-twentieth normal, a twentieth normal solution of sodium hydrate was made and then adjusted so that one volume neutralized the same quantity of diluted hydrochloric acid as an equal volume of lime water.

Cow's Milk.—The fat and total solids were determined by the Babcock methods.

Breast Milk.—Not enough could be obtained to enable an estimation of fat and total solids to be made. Sometimes not over 15 or 20 c.c. could be obtained.

Method of examination.—In the case of cow's milk, the fat and total solids were first determined and then the reaction to *neutral* litmus paper. Breast milk was pumped into sterile beakers, the breast being emptied as completely as possible, and tested with red and blue litmus paper at once. 10 c.c. of milk were then placed in each of two white dishes, and one drop of the phenolphthalein solution added. Lime water was then added with a pipette graduated to 0.1. c.c. The tests were made in duplicate, and two and sometimes three of us were present, so as to reduce the personal factor in judging of the color changes. In a few cases it became necessary to use 5 c.c. of breast milk instead of 10 c.c. in making the test, as 20 c.c. were not obtained.

These tables show the results of the examinations:

In the midst of the examinations the supply of red litmus paper became exhausted, and more was ordered from the maker of the previous lot—one of the most reputable manufacturers in the United States. Whereas breast milk had been alkaline to the previous lot of red litmus paper it did not change the color of the new. It was hardly possible that all the breast milks had changed, so a visit was made to the manufacturer, who insisted that the paper was "all right." After some argument a small quantity like the former lot was found in his stock and purchased. When strips of the two lots of red litmus paper were dipped into breast milk it was found that one was turned faintly blue while the other remained unchanged. This may explain the statements found in nearly all textbooks that breast milk is neutral or faintly alkaline. It is easy to see from this what opposite statements as to the reaction of milk are possible when the litmus paper of even the most reputable manufacturers is used.

The following table shows the wide variation in results obtained with the two lots of litmus paper:

| Date | Kind of Milk. | Reaction to NeutralLitmus Paper. | Per Cent. Lime Water to Render Alkaline to | | |

| 5- 4-'03 | 5c. Grocery | Neutral | 80 | 35 | 80 |

*Two strips from same bottle.

To make clear the apparent inconsistency of milk of alkaline or neutral reaction to litmus paper requiring large quantities of lime water or other alkali to make it alkaline to phenolphthalein, it may be stated that during the past few years the conception of acids and alkalies has changed greatly.

According to the theory of ions, al neutral salts when dissolved in water undergo a change in which part of the salt becomes electrically dissociated, one portion of the salt carrying a charge of positive electricity and the other portion carrying a charge of negative electricity. These electrically charged substances are called ions, and most chemical reactions are supposed to consist of negatively charged ions neutralizing positively charged ions.

A compound which when thus electrically dissociated in an aqueous solution splits up into hydrogen and another atom or group of atoms is called an acid, *e.g.* H + Cl, or $H_2$ + $SO_4$. It may or may not redden litmus paper. A compound that in aqueous solution, splits up into hydroxyl (OH) and another atom or group of atoms is called an alkali or base, *e.g.* K + OH. It may or may not turn litmus blue.

Just as some salts are sparingly soluble in water while others are freely soluble, so some salts are very slightly converted into ions while others are freely converted into ions.

A strong acid or base is one that is freely changed into ions in aqueous solution; a weak acid or base is one that is ionized to a very slight extent only. For instance, hydrochloric acid perfectly free from water will not redden litmus paper, attack metals, or show any properties of an acid and can be stored in iron vessels, but when dissolved in water it is almost completely changed into H + Cl ions and becomes one of the strongest acids known, readily dissolving iron or other metals.

Boracic acid is converted into ions to a very slight extent only and is therefore a very weak acid.

To determine the point where an acid or alkali is neutralized a substance is added which takes no part in the reaction but which will produce a color as soon as an excess of acid or alkali is present. Such a substance is called an *indicator*.

Indicators are either weak acids or bases, and generally combine with the acid or alkali to form colored compounds.

Litmus is a substance that apparently acts either as an acid or base. The aqueous solution of litmus is of a violet color and forms blue compounds with strong alkalies and red compounds with strong acids. To get a red or blue color the acid or alkali must be stronger than the litmus.

Red litmus paper represents litmus acted upon by hydrochloric acid. Blue litmus paper represents litmus acted upon by sodium or potassium hydrate. Neutral litmus paper has a reddish violet color and turns bright red with strong acids or blue with strong alkalies.

When a strong acid is added to a solution of bicarbonate of sodium the carbonic acid being weak is displaced and is given off as a gas. Now there are many acids that are weaker than litmus. If a strip of litmus is dipped into a solution of a neutral salt of one of these weak acids it displaces the weak acid just as the strong acid displaces the carbonic acid of bicarbonate of sodium and combines with its base to form a blue salt, and the solution is said to be alkaline when in reality it was neutral. In this case the litmus did not act as an indicator, but as a precipitant.

Phenolphthalein is an acid very much weaker than litmus, and of course can not combine with alkali until all stronger acids present, including litmus, are neutralized; therefore phenolphthalein will show the presence of acid when litmus shows the presence of alkali, owing to its taking part in the reaction and displacing the weak acid. This is well illustrated by saliva containing thickened mucus. It is alkaline to litmus paper, but we found it required 70 per cent. of lime water to render it alkaline to phenolphthalein. The more mucus that was added to this saliva the more lime water was needed to cause an alkaline reaction to phenolphthalein and the greater was the thickening of the solution. The mucin which swelled up and combined with the lime was an acid stronger than phenolphthalein, but weaker than litmus. We were satisfied that a large part of the acidity of fresh milk to phenolphthalein was due to the presence of mucin, as the more lime water the milk took the thicker it became.

The fact that many acid solutions react alkaline to litmus is well known to bacteriologists. Eyre states that in making meat extract and other culture media the reaction should be determined to phenolphthalein, as the media will react alkaline to litmus while yet quite acid, as "litmus is insensitive to many weak organic acids, the presence of which is readily indicated by phenolphthalein."

There are many salts of strong bases with moderately strong acids, that in aqueous solution show an alkaline reaction to litmus and acid reaction to phenolphthalein. The cause of this is that litmus can displace portions of the acid and combine with the alkali, but the phenolphthalein is too weak an acid to do this. In solutions of salts of strong alkalies with very weak acids (carbonic, boracic, etc.), the base is ionized so much more completely

than the weak acid that it decomposes the water and free alkali is formed with which phenolphthalein can form a colored salt. Borax and potassium carbonate are examples.

It is probably owing to the fact that there is generally some carbonic acid present in the milk that there was more lime water than sodium hydrate needed to render the milk alkaline. The calcium carbonate formed would be precipitated while the sodium carbonate, as soon as formed, would be hydrolyzed and react alkaline.

The amphoteric reaction of milk to litmus paper is explained by Richmond as follows: "Litmus is an indicator of the medium class, *i. e.* it is unaffected by weak acids, and incompletely affected by acids of medium strength. Litmus paper may be either red, containing only the acid, or blue, containing the acid with such an amount of alkali that no red ions are formed, or at some intermediate stage. If we test with these papers a partially neutralized mixture of acids of various strength, we may obtain quite contradictory results. Phosphoric acid is a good example of three different acidities in one molecule; the first acidity is strong, the third is very weak; and the second is intermediate between the two, and about equal in strength to the acid of litmus. It has been shown that milk contains phosphates with the third acidity completely neutralized, and the second only partly so, and therefore milk is an excellent substance to show the peculiar behavior of litmus. If we take a blue litmus paper and dip it into milk, the blue litmus having the acid completely neutralized is more alkaline than the milk, and the two tend to come into a condition of equilibrium by a portion of the alkali of the litmus passing to the milk; the consequence is that the litmus becomes less alkaline, and turns slightly red. If we take a red litmus paper, which is more acid than the milk, alkali will tend to pass from the milk to the litmus, and turn it slightly blue. This is the so-called amphoteric reaction. A litmus paper of some intermediate stage would be unaffected. It is therefore quite fallacious to try and test the acidity of milk with litmus paper; the old test to see if milk is acid by putting in a piece of blue litmus paper has long been discarded by scientists, but unfortunately is still recommended by those who have the little knowledge which so often proves a pitfall; with a suitable litmus paper all fresh milk can be condemned by this test, while, by judiciously changing the paper, milk which is on the turn can be triumphantly proved fresh."

Having found that breast milk and cow's milk were both normally acid, and that the alkaline reaction of breast milk and amphoteric reaction of cow's milk to litmus had no practical significance and were due to the excess of phosphate of calcium in cow's milk and the chemical action of the litmus on the breast milk, an attempt was made to see what was the effect of the addition of lime water and bicarbonate of sodium which is advocated as a means of making the reaction of cow's milk to litmus correspond to that of breast milk.

It is generally recommended that 5 per cent., 10 per cent., and sometimes 25 per cent. of lime water be added to the infant's food, or 1 to 2 grains of bicarbonate of sodium to each ounce of food. As antacids there is here a great disproportion, as a 20-ounce mixture containing 10 per cent. lime water would contain about 1½ grains calcium hydrate or 40 grains bicarbonate of sodium. A small quantity of filtered sour milk which contains lactic acid, or a stronger acid added to feedings containing bicarbonate of soda, caused an effervescence, which shows that the soda had not acted as an antacid, but remained unchanged in the feeding.

Some fresh milk of the best quality was diluted four times with water to approximately 1 per cent. proteids, and to an ounce of this a few drops of dilute rennet solution which was not acid were added and the milk was gently warmed; a solid curd formed.

To other portions were added, 5 per cent, 10 per cent., 15 per cent., and 20 per cent. of lime water; ½, 1, 1½, and 2 grains of bicarbonate of soda to the ounce; ½, 1, 1½ and 2 grains carbonate potassium to the ounce; and ½, 1, 1½, and 2 grains phosphate soda to the ounce. The same quantity of rennet was added to each, and all were warmed as in the control. The curds with 5 per cent. and 10 per cent. lime water and phosphate of sodium were much softer and more flocculent than in the control. With one grain bicarbonate of soda to the ounce a very flocculent curd formed; with 2 grains only a trace of curd appeared. No curds formed with 15 per cent. and 20 per cent. lime water, or even with ½ grain carbonate of potassium to the ounce. When a small quantity of very dilute hydrochloric acid, not enough to precipitate the casein, was added, rennet curds formed. The curd of the milk containing bicarbonate of sodium was rendered spongy by the bubbles of gas produced by the action of the hydrochloric acid on the bicarbonate of sodium. Lime water caused the milk to swell up; none of the other additions did.

Tests were also made with some "grocery milk" containing fat 3.2 per cent. and solids not fat 8.54 per cent., which required 80 per cent. of lime water to render it alkaline to phenolphthalein with the following results:

| | | |
|---|---|---|
| 1 oz. whole milk + rennet | | = dense curd. |
| 1 oz. " " " + | 10 per cent. lime water | = less dense curd. |
| 1 oz. " " " " | 20 " " " | = still less dense curd. |
| 1 oz. " " " " | 30 " " " | = jelly. |
| 1 oz. " " " " | 40 " " " | = thin jelly. |
| 1 oz. " " " " | 70 " " " | = no curd. |
| 1 oz. " " " " | 2 grs. bicarb. soda | = soft curd. |
| 1 oz. " " " " | 4 " " " | = jelly. |
| 1 oz. " " " " | 6 " " " | = thin jelly. |
| 1 oz. " " " " | 8 " " " | = no curd. |
| 1 oz. " " " " | 1 gr. borax | = jelly. |
| 1 oz. " " " " | 2 " " | = no curd. |

In high dilutions of milk (.5 per cent. proteids) the addition of 10 per cent. lime water, as is recommended, is equivalent to adding 70 per cent. to 80 per cent. to the undiluted milk, which would make it decidedly alkaline in most instances, and absolutely inhibit the formation of curds. The addition of 2 grains bicarbonate of sodium to the ounce of the same dilution would be equal to .14 to 16 grains to an ounce of whole milk, or more than double the quantity required to inhibit the formation of curds.

It has been denied that lime water had any effect as a diluent, serving only to reduce the acidity of the stomach. Experiments on which such statements are based were made on cats or dogs, adult carnivorous animals, whose gastric juice is very acid. A baby's stomach is undeveloped, and does not secrete much acid, and therefore can not be compared with a cat's or a dog's stomach. Clinically, good results are often seen from the use of lime water and bicarbonate of sodium in milk, and the result can not come from the slight antacid value of the lime, or that of the bicarbonate of sodium, for this remains unchanged in the milk, but must come from the retardation or inhibition of the formation of curds.

*Conclusions.*—1. Breast milk and cow's milk are both acid.

2. The litmus paper test for milk is unreliable because of the variation in the quality of litmus

paper, and the litmus taking part in the reaction and not acting as an indicator.

3. The effect of adding lime water or bicarbonate of sodium to feedings is to retard or inhibit the formation of curds by rennet.

4. The teaching that lime water, bicarbonate of sodium, or carbonate of potassium should be added to fresh milk or feedings simply because they are antacids is erroneous.

5. The addition to milk or feedings of alkalies or salts that become alkaline in solution is an empirical method of aiding digestion by preventing the formation of dense curds that would slowly leave the stomach and be difficult of digestion in the intestine.

## THE INFLUENCE OF HEREDITY ON THE EYE.

By JOHN E. WEEKS, M.D.,
NEW YORK.
SURGEON OPHTHALMIC DEPARTMENT, NEW YORK EYE AND EAR INFIRMARY.

The transmission of peculiarities of form and function, of tendencies to degeneration and to disease, from parent to child for some generations affects the eye as well as other parts of the human body. The form, the color, peculiarity of movement, as well as peculiarities of the deep tissues of the eye, are largely influenced by heredity. Consanguinity in the parents accentuates the hereditary tendency. In the greater number of cases of hereditary malformation, it is not so much that the defect is handed down from generation to generation through a long line, as that the children of one union, because of some peculiarity of mother or father, all or part suffer.

*Eyelids.*—Of the congenital peculiarities of the eyelids, the conditions known as epicanthus and ptosis are the only ones that can be said to be hereditary. Steinheim (*Centralblatt für praktische Augenheilkunde*, XXII, p. 249) reports the case of a family in which epicanthus and ptosis occurred fifteen times in the course of five generations. It is well known that in the Mongolian race epicanthus is a racial peculiarity.

*Coloboma of the Iris.*—McGilliray (*Ophthalmic Review*, XVII, p. 1) gives a genealogical tree of three generations with coloboma of the iris, five females and one male being affected. In some of the cases there was upward coloboma with subluxation of the lens downward. De Beck (*Archives of Ophthalmology*, XV, 1, 8) records a history of coloboma of the iris occurring in two generations of a family.

*Aniridia* (irideremia, absence of iris).—Gutbier (von Ammon's *Zeitschrift*, V, p. 78) gives the history of a family of eight children in which three males had this defect. One of these had four sons, three of whom suffered from total aniridia, one partial aniridia. The children and grandchildren had normal eyes. Of the children of one of the other brothers, a boy had normal eyes and a girl was without irides. A daughter of a third brother suffered from absence of irides. A total of ten cases in four generations.

De Beck (Transactions American Ophthalmological Society, 1894) reports the case of two brothers, one with aniridia and one with downward coloboma of the iris. The brother with coloboma had a son with aniridia. The brother with aniridia had a family of nineteen children, one son with aniridia and one with coloboma. The other children had normal eyes. The son with aniridia had six children; of these two sons and one daughter suffered from aniridia. The son with coloboma of the iris had five children; of these one daughter suffered from aniridia. The eyes of the others were normal.

Lang (Transactions Ophthalmological Society, U. K., X, p. 207) reports a case of the occurrence of aniridia in two members of a family of three. The paper of Lawrentjeff (*Centralblatt für Augenheilkunde*, IX, 10) shows conclusively that the affection aniridia is often hereditary. Aniridia and coloboma of the iris appear to occur more often in males, and, judging from reported cases, the line of descent is on the male side.

*Polycoria.*—It is doubtful whether this condition is ever hereditary. Mittendorf (Transactions American Ophthalmological Society, III, 735) describes two cases occurring in father and daughter, which suggests heredity.

*Coloboma of the choroid* due to heredity has been observed. Manz (*Græfe Sæmisch.*, Bd. II, T. 2, p. 86) refers to a case in which son, father, and grandfather were affected and to other cases in which a number of the children in a family presented coloboma of the choroid, the same condition being present in one of the parents.

*Inherited peculiarities of the cornea* are extremely rare, except as they are the result of inherited disease or of conditions affecting the entire globe. Oliver (American Ophthalmological Society, 1892) reports symmetrical opacities of the cornea occurring in mother and son.

*Albinism.*—Absence of pigment in the eye as well as other parts of the body occurs in races of all colors, and is often, but not always, hereditary. Crocker ("Diseases of the Skin," third edition, p. 674) states that "heredity is the only known cause of the complete form."

*Globe.*—Malformations of the globe due to heredity have been observed. Brouner (Rep. Ophthalmological Society, U. K., p. 439) reports two families with bilateral microphthalmus and cataract. In one case the father and four of eight children were affected. No consanguinity or history of syphilis. In the other case the mother and all of the children, four in number, were similarly affected. The mother of the woman is said to have had similar eyes.

Certain disease conditions of the eyes developing early or late in life, not due to inherited *disease* or to consanguinity of parents, but in which heredity is a strong factor, may now be mentioned.

*Lens.*—Wilson (*Journal of Ophthalmology, Otology, and Laryngology*, October, 1891) gives the history of the descendants of an individual who suffered from congenital cataract. Of thirty-one descendants running through four generations, sixteen were affected with congenital cataract, males and females in equal proportion. Tromaget (*Annales d'Oculistique*, CX, 200) found compound lamellar cataract in members of a family through six generations, females only being affected. He ascribed this case to heredity alone.

Derby (Transactions American Ophthalmologic Society, 1891) reports eight cases of zonular cataract among the members of a family. The cataract occurred in females almost entirely. Derby is of the opinion that such faults of development are more apt to be transmitted through the female and are more complete in the female than in the male.

Schanz (*Centralblatt für Augenheilkunde*, XXI, p. 264) mentions a family of three children, all of whom became blind at about the twentieth year from cataract. The mother was healthy.

Berry (*Ophthalmic Review*, VII, 1888) reports that in a family of fifty-five members, running through five generations, eight males and five females were affected with cataract. Not all were congenital. Berry terms many of these cases premature senile cataract.

The experience of oculists who have observed many cases of disease of the eyes leads them to conclude that in many cases, particularly those occurring relatively early in adult ife, heredity often exerts a strong influence, depending on what might be termed an inherited vicious habit of the system.

*Optic Nerve.*—Well-authenticated cases of optic-nerve atrophy occurring in members of a family throughout a number of generations, without consanguinity of parents or history of syphilis, are on record. The statement usually made is that the families possessed strong neurotic tendencies. The affection appears as an optic neuritis of mild degree and proceeds to partial or complete atrophy. Individuals are affected from the age of eight to thirty-five years (Norris). Batten (Transactions Ophthalmological Society, U. K., XVI, p. 125) reports the case of a mother whose sight began to fail at the age of twelve years; the daughter had distinct atrophy at the age of ten years. No general disease. Somys (*Zehender's klinische Monatsblatt*, XXX, p. 168) reports having traced optic neuritis through three generations; males only were affected. Story (*Ophthalmic Review*, 1885, p. 33) quotes Leber as having records of fifty-five cases occurring in sixteen families. Story reports five cases occurring in one family; the two that he observed developed central scotoma. Norris (Transactions American Ophthalmological Society, 1884) examined the eyes of three generations of a family in which optic-nerve atrophy was hereditary. The symptoms were, frequent frontal headache and gradual loss of central vision. There was contraction of the fields of vision for form and for colors yellow, blue, and red, in the order given. Three stages of the development of the atrophy were noted: (1) Cloudy swelling; (2) "lymph reflexes along the course of the retinal vessels"; (3) gradual death of the nerve tissue. Two cases ended in blindness. Some improved under the use of strychnia. From the recorded histories of these cases it appears that the affection is really a retrobulbar neuritis in the beginning.

*Retina.*—Of the affections of the retina in which heredity plays an important part in the etiology, hemeralopia, the amaurosis of amaurotic family idiocy, and retinitis pigmentosa may be mentioned.

Heredity is by no means a frequent causative factor in the production of hemeralopia, but it is occasionally so. Sedan (*Rec. d'opht.*, November, 1885) reports the case of a family in which, of twenty-nine members, nineteen were hemeralopic.

The other hereditary affections of the retina may be considered in the class of hereditary eye diseases which are apparently influenced largely by consanguinity and racial peculiarities. Amaurotic family idiocy, in which a prominent feature is the disease of the retina, occurs almost invariably in Hebrews, and is strongly influenced by family peculiarities; thus the twenty-three cases mentioned by Swanzy (Norris and Oliver, Vol. IV, p. 626) occurred in eleven families.

Retinitis pigmentosa has long been considered a disease in which consanguinity of parents plays a strong rôle in the etiology, but recent investigations place consanguinity in a very minor position in this respect, heredity being accorded the first place. Ayres (*American Journal of Ophthalmology*, 1886) reports 25 cases occurring in 19 families—18 males and 7 females. The parents were related in 28 per cent. There was a tendency to glaucoma in 3 families. Siegheim (Inaugural Dissertation, Berlin, 1887) reports 73 cases. He finds little support for the theory of consanguinity; he considers heredity to be a strong etiological factor. Of 11 cases of retinitis pigmentosa reported by Trousseau, only two had parents who were related. Liebreich was of the opinion that consanguinity could be demonstrated in 50 per cent. of the cases of retinitis pigmentosa, but more recent investigations have shown conclusively that this percentage is too high, the percentage being only about 25. The male sex is more frequently affected than the female, and the disease is more common with the Semetic than with the Aryan race (Schöbe).

Diseases that are closely allied to retinitis pigmentosa also largely influenced by heredity are the retinal degenerations presenting the symptoms of retinitis pigmentosa, but without pigmentation of the retina, and the condition known as *retinitis punctata albescens*.

*Glaucoma.*—This most important disease is influenced by heredity and by racial peculiarities. Von Graefe called attention to the influence of heredity in glaucoma many years ago. In the cases in which heredity is a factor the disease manifests itself early in life. Harlan (*Journal of the American Medical Association*, September 12, 1885) records the history of a family in which glaucoma occurred in nine members in five generations. The time of the development of the disease in four of the patients is given as one at seventeen, one at eighteen, and two at nineteen years of age. Howe (*Archives of Ophthalmology*, XVI, 1, 72) reports eight cases in three generations. Of a family, one of the members of which came under the observation of the writer, five members were affected in three generations. The percentage of cases of glaucoma due to heredity is small, but is sufficiently large to merit consideration. Knapp has called attention to the fact that glaucoma is more frequently met with in Hebrews, in and about New York at least, than in individuals of other races, and Brugsch-Bey found a higher percentage among Egyptians than is found among Europeans.

*Hydrophthalmus* (buophthalmus), a condition that has received the name of congenital glaucoma, is also strongly influenced by heredity.

By far the most common cause of disease of the eye due to heredity is syphilis. In 212 hereditary syphilitics, Fournier found the eye affected in 101 (Norris & Oliver, Vol. II, p. 440). Girls suffer more severely than boys.

A list of the affections of the eye due to inherited syphilis follows:

Alopecia affecting lids and brows.

Choroiditis, presenting mixed forms, occurring either as a congenital condition or before the twenty-fifth year, affects both eyes usually, however it may be confined to one eye.

Erythema of the lids, early in child life.

Iritis, acute, occurring in the first months of infancy.

Iritis, gummatous, occurring in the early years of childhood.

Eruptions, nodular, vesicular, papulo-squamous, all affecting the eyelids and occurring in childhood.

Optic-nerve atrophy, occurring congenitally or in the early years of life.

Ophthalmoplegia externa, rarely.

Palsies of eye muscles, nuclear.

Palsies of eye muscles, peripheral, occurring in childhood.

Parenchymatous keratitis, seldom before the age of six years and only very rarely after the age of thirty-five. Hutchinson narrates one case occurring at the age of sixty.

Periostitis of the orbit, in early childhood, pursuing an acute course.

Retina, pigment degeneration of (pseudoretinitis pigmentosa).

Retinitis, hemorrhagic.

Rupia, affecting the lids.

Tarsitis, occurring in early childhood, usually bilateral.

The transmission of faults in the shape of the eye, whereby the various errors of refraction, hypermetropia, myopia, and astigmatism recur in the offspring, is not unusual.

Muscular anomalies, particularly the various phorias, are not infrequently transmitted.

Color-blindness of all degrees is also strongly influenced by heredity. Reber (*Medical News*, January 26, 1895) mentions the occurrence of color-blindness in six women in two generations of a family. After giving the histories of a number of families in which color-blindness was hereditary, Jennings ("Color-vision and color-blindness," p. 41) sums up as follows: "Color-blindness is hereditary and attached to certain families. It may not be found in one generation, but reappears in the next. All the children will not be affected, the girls especially escaping. When several children are affected it is traceable to the mother. The kind and degree will be the same for all the cases in a family."

It will thus be seen that heredity influences the eye in respect to form and disease in no inconsiderable degree.

## TREATMENT OF TRACHOMA.*

By J. HERBERT CLAIBORNE, M.D.,
NEW YORK.

In order that I may properly present the subject that has been relegated to me, namely, the treatment of trachoma, it is necessary that it should be stated first of all what trachoma is. This matter has already been ably set forth to-night by others. Nevertheless, in order that I may handle my subject in a sequential manner, I feel constrained to present the clinical picture of trachoma from my own standpoint. Of course, trachoma is acute or chronic, but for the sake of this discussion I divide it into the non-inflammatory and the inflammatory forms.

The non-inflammatory form is characterized by the existence of sago-like grains on the mucous surface of the upper and lower lids. I wish to lay particular stress upon the fact that the granulations must be both on the upper and lower lids. The form of trachoma which is known as follicular, in my opinion, is restricted to the lower lid and is particularly seen toward the outer canthus. Whether or not this form of trachoma is the beginning of the non-inflammatory form I do not know. The granulations on the upper lid are sometimes not observable until the lid is turned, because they are restricted to the retrotarsal fold. On eversion, however, of the upper lid they can be seen in great abundance in the cul-de-sac, but they do not occur in the depths of the sulcus. The picture presented by this form of trachoma is so marked, when typical, that no one could fail to recognize it. For my own part, I regard this form of trachoma as distinctly contagious, and therefore it should be removed at the earliest possible moment for the sake of the body politic and of the individual.

The other form of trachoma is sometimes known as Egyptian or military ophthalmia—though I see no reason for applying either term, inasmuch as it occurs elsewhere than in Egypt and among other bodies than soldiers. Its onset is characterized by acute inflammation, lacrymation, photophobia, and a great amount of discharge. Subsequently granulations form on the upper and lower lids, both on the exposed surfaces and in the retrotarsal folds constituting the primary form of the disease. The secondary stage is that in which the granulations coalesce, are no longer discrete, and the final stage is the cicatrization of the lids with pannus and opacity of the cornea.

It is well known, and has been observed here to-night, that the cause of the trachoma is not known. But it is a significant fact, as will be pointed out later, that mechanical treatment is the best and most efficient for a disease which is entitled to the suspicion of being microbic in origin.

The treatment of all trachoma may be divided into medical and surgical, and it is safe to say that almost all of the known remedies that are astringent have been employed with more or less beneficial effect. It requires no patriarchal experience to recall the time when the use of gonorrhœal matter placed in the conjunctival cul-de-sac was employed in cases of trachoma which were attended with pannus and cicatrization. This barbaric and criminal form of treatment has been finally relegated to the lumber room of therapeutic antiquity. Following that and just a little less severe and grievous was the use of the powder or watery extract of the juquirity, or abrus precatorius bean, which possesses the power of inciting a violent inflammation of the lids—an inflammation, indeed, which can hardly be differentiated from that produced by the gonococcus. This remedy should be employed, if ever, only in those cases in which there is dense pannus and keratitis, and in such selected cases beneficial results have been encountered on many occasions. This treatment at first blush would seem entitled to consideration, but the loss of an eye in Paris, followed by the loss of two eyes in this city, in the hands of eminent authorities, has checked enthusiasm, so that to-day it may safely be said that the use of the abrus precatorius bean no longer plays a rôle in the treatment of trachoma.

Silver nitrate has always been a favorite remedy in the hands of those who have not met with the most violent forms of trachoma. I have heard Hirschberg of Berlin say that he could cure all cases of trachoma with a one to two-per-cent. solution of silver nitrate. Obviously his experience with the severer forms of trachoma is rare, and that explains his attitude. Silver nitrate is of but slight value in the treatment of real trachoma, and, in my opinion, is not entitled to serious consideration. The use of zinc as a palliative and supplement to severe measures is to be commended. Bichloride of mercury in stronger or weaker solutions has likewise been employed, and lately the modern combinations of silver with egg albumen have been used with some putative benefit. The most recent remedy employed is the citrate of copper. With this I have had no experience. Formalin, in the strength of 1-5,000 to 1-10,000, has been used lately with benefit in the hands of several surgeons. Of all remedies used, however—one that has proved itself of inestimable value, and, in fact, is the *vade mecum* in the treat-

*Read before the Medical Society of the County of New York.

ment of trachoma—copper sulphate stick stands preëminent. This copper stick, or copper crystal, should be ground smooth and in the shape of a parallelogram, and should be so thin that it can be introduced under the upper lid without the use of undue force or traction. This should be placed in a porte crayon and applied as follows: The upper lid being everted, the stick should be applied delicately and gently underneath the lid in the cul-de-sac. I consider it unnecessary to touch the outer surface of the everted upper lid. Subsequently the cul-de-sac of the lower lid should be gently stroked with the stick. It will then be observed that the tears have produced a solution of the copper. The excess should be thoroughly wiped away, and when this is done the entire amount of copper placed upon the eye will be to some extent diminished. When this is done delicately and lightly, the pain following the procedure is, in some cases, slight, but in others it is considerable; in the majority of cases it is not so severe as is generally supposed, and much can be done to prevent pain by the delicacy of manipulation on the part of the surgeon.

I lay particular stress upon putting the stick underneath the upper lid, for if this is not done the desired effect will not be obtained.

I also wish to register my opinion against the use of the camel's hair brush. I consider it impossible to disinfect these brushes properly without destroying them. A cotton armed probe is the safer adjuvant.

Of course, the hygienic surroundings of the patient should be regarded. Dust, smoke, vitiated atmosphere should be avoided and the general health and cleanliness of the individual should be promoted. But when we reflect that all cases of trachoma we meet with occur in people who live under conditions in which it is impossible not only to produce asepsis in the surroundings, but even difficult to obtain cleanliness, we simply make this suggestion as a matter of conscientious detail and without any hope or expectation of its being followed out.

It frequently happens, however, that patients who have been cured or practically cured a number of times of trachoma get well only after entire change of surroundings.

Without loss of further time we will proceed to the surgical treatment of trachoma. Surgical treatment depends upon the kind, extent and stage of the disease and upon its intensity.

The first form—that with sago-like grains—is the form in which surgical treatment is most brilliant. Before speaking of the method which, up to the present time, seems to me the best, I will refer to the various methods in vogue before the last and best was devised. Possibly the oldest mechanical method is that of grattage or brossage—brushing or scratching the granules, which dates back to early times and has been referred to by Borelli in 1859, and Schroeder in 1889. This has been employed with some success in the hands of a number of surgeons in this city at the Eye and Ear Infirmary. It has been used with and without scarification. A coarse tooth brush was used, and after scrubbing the surface of the lids with this brush a solution of 1-500 bichloride of mercury was rubbed in. At first simple scrubbing was employed, later an instrument was devised and scarification preceded the scrubbing. The after-treatment consisted in the application of astringents and aseptic washes, among which was copper sulphate. It is fair to say that this method has been eliminated from surgery, except in the hands of a few men, and now has only an historical value. Salmonsohn has employed the galvano-cautery and was accustomed to burn out the granules with a looped electrode. I myself have frequently used the actual cautery with a platinum probe, invented by Dr. Gruening of this city, and have had considerable success with it in past years but have abandoned it entirely. Electrolysis was introduced by Lindsay Johnson of London. He was accustomed to scarify the granulations with a silloneur, a scalpel with three parallel blades, and afterward apply the electrode along the lines of incision. The most irrational form of treatment yet suggested was that of Galezowski of Paris. I refer to the excision of the strip of conjunctiva containing the granules. I cannot see that this commends itself to anyone who has in view the preservation of the normal structure of the tissue involved. Another operative procedure is curetting, advocated by Bardenheuer of Cologne, and Sattler of Leipzig. After cocainization or general anæsthesia, the capsule of each granule is ripped up and its contents expressed or scooped out with a tiny spoon. This seems needlessly long and tiresome, and does not commend itself to reason. Dr. Jameson of Brooklyn has invented a scarifier which consists of a number of pyramidal elevations arranged on a metal surface and pointing in different directions. He claims the advantage of removing only the granulations and not injuring the submucous tissue. A number of operations may be necessary to effect a cure.

The use of scissors for cutting away the follicles was at one time in vogue, but this method soon fell into disuse on account of the destruction of the submucous tissue which frequently followed it.

I reserve the most reasonable, thorough and effective form of treatment for the last. This is known as "expression." Cuignet described it as early as 1873. It was recommended also by E. Berlin, Mandelstamm, and Hotz. The latter was accustomed to express the granules with his finger nails. Most of us have kept pace with the development of this form of treatment. In 1891 Dr. Prince invented a ring-shaped forceps which he used in trachoma, and about the same time Dr. Noyes invented an instrument for the expression of non-inflammatory trachoma, used with some success in the New York Eye and Ear Infirmary. Prince's forceps are—except those I am about to describe—the best. The instrument of Noyes I consider harmful except in the most skilful hands. It remained for Dr. Knapp to cap the climax by constructing what is known as the roller forceps. As Hirschberg has remarked, this instrument is the only new thing which has been introduced in the treatment of trachoma in the last twenty years, and if this distinguished patriarch of ophthalmology, Dr. Knapp, had never done any other thing he would yet have written his name amongst the immortal ones of medicine. The instrument consists of a pair of fluted cylinders 2-3 mm. thick, and 10-11 mm. long, which roll on pivots on the horse-shoe-shaped ends of the shafts of the forceps. In order to be good, the cylinders must roll easily. The granules are rolled between the cylinders and their contents are expressed. The object is to bruise and break down the granules and squeeze out their contents. They are an instrument of force, and not of laceration.

The technique of the operation is, to some extent, the following: The upper lid having been everted, the folded edge of the conjunctival surface is grasped with a fixation forceps and pulled upward and outward. The rollers are then applied to the mucous surface of the lid folded upon itself and this is squeezed between the cylinders and the granules are expressed. When all granulations are expressed, as shown by smoothness of the lid, the lower lid is

treated in such a way that the granules are destroyed and the methods by which these two simple acts are achieved are different in the hands of every operator I have seen work. Suffice it to say that so long as the granules are destroyed without laceration of the membrane the end is achieved.

There have been a number of modifications of Knapp's roller forceps, and one which I will particularly mention is that of Dr. Campbell, in which the ends of the cylinders project beyond the tip of the shaft, and another of Dr. Rust, in which the horseshoe-formed end-piece has one arm in a straight prolongation of the shaft while the other turns off parallel with the cylinder, leaving a slight space between it and the cylinder. I do not think these possess any advantage over Knapp's forceps.

I have the honor to present to you to-night a case of instruments for the operation of trachoma, which consists of a pair of fixation forceps of stronger grip and bite than those ordinarily used, and two roller forceps in some respects a modification of those of Dr. Knapp. The first pair differs from Knapp's only in this respect that the cylinders instead of being fluted have parallel lines of roughened elevations or nodules upon them, so that in rolling they not only express the material but also rupture the surfaces of the granules and allow of easier "expression." The distinct advantage of this forceps in my hands is that less force is required to destroy the granules, and after operation there is an absence of the bruised, swollen appearance consequent upon the use of Knapp's instrument. I wish to lay stress upon the fact that with this forceps in my hands the operation has been achieved more quickly, easily, and thoroughly than with any other. The other forceps to which I call your attention is exactly like the one just described, except that the horseshoe containing the rollers has been bent to a right angle to the handle. I find this an advantage in getting into the outer and inner canthi, the hand being out of the field of operation.

Unfortunately a general anæsthetic is necessary, and ether appears to be safest. Cocaine solution is of no value, but lately the powdered crystals have been used on the surface of the lids with some success. Latterly Dr. Coburn and myself have been experimenting with ethel chloride. If this anæsthetic be administered as generally employed for two or three minutes and then the ether pushed, general anæsthesia can be induced in from two to five minutes. The patients recover more rapidly and, as a rule, neither vomit nor exhibit so much excitement as with ether alone.

There exists a difference of opinion as to the best after-treatment. Many rub into the lacerated conjuctiva strong bichloride solution or the solid stick of copper. I have never employed these methods. I have observed that in the hands of others this treatment is followed by great reaction. I consider it entirely unnecessary. I direct the parents simply to keep the eyes clean for a day or two, and I prescribe zinc or acid boric till the post-operative membrane is gone. I then apply silver nitrate in one-per-cent. solution for a few days and subsequently copper sulphate in solid stick till I am convinced the case is cured. I always send my patients home as soon as they can walk. I see no reason for keeping them in wards over night.

Concerning the second form of trachoma, Egyptian or military ophthalmia, medicinal treatment seems, in general terms, to be of the greatest service, except when the granules are distinct and definite, whether discrete or confluent, and it has been my custom to "express" these cases as long as I could see any granules at all. When the lid has become cicatrized and the cornea clouded it is useless to attempt expression. Cases of that description should be treated only medicinally, and bluestone is the remedy *par excellence*.

It is the custom of some to use atropine in all cases of trachoma in which there is pannus, alleging that iritis is generally present at the same time. This may be true and in such cases atropine is indicated, but in my experience iritis is exceedingly rare in trachoma, and it is my practice never to use atropine unless there is unmistakable evidence of the existence of iritis. Atropine itself is an irritant and seems to be distinctly contraindicated. The use of bluestone in this condition supplemented by zinc, boric acid and bichloride of mercury is, I believe, the accepted form of treatment to-day.

To sum up: The treatment of trachoma is medicinal or surgical or a combination of the two. In the non-inflammatory form—that characterized by the frog-spawn granulations—the operation of expression alone followed by appropriate after-treatment is indicated.

The best instrument at present in vogue in my opinion is the roller forceps of Knapp or some modification of it.

In the inflammatory form, the so-called military ophthalmia, the operation of expression as described above, followed by mild astringents and finally by the copper stick, is indicated, as long as there are granules in reasonable quantity. When the disease has passed the granular stage and is in the cicatricial, copper sulphate alone or in combination with other remedies is indicated.

30 West Thirty-sixth Street.

## ELECTRICITY IN THE TREATMENT OF DISEASES OF THE STOMACH.

By E. G. MARSHALL, M.D.,
WALLINGFORD, VT.

In the Medical Record of May 9, 1891, Max Einhorn published a paper entitled "A New Method of Direct Electrization of the Stomach." In this paper he described his "Deglutable Electrode," and gives a report of the physiological action obtained by using intragastric electricity on three persons having no digestive trouble, and also gives a résumé of his clinical treatment of several cases suffering from various stomach diseases. Previous to the publication of this paper, intragastric electrization had not met with much favor, owing to the imperfection of the electrodes then used.

Percutaneous electrization, however, had many advocates, and good results were reported by A. D. Rockwell and Beard in the *Phil. Med. Surg. Report* of 1868, No. 20, and in 1871, page 470, of the same journal. Neftel in 1876 says: "For more than eight years I have used the induced current in the treatment of dilatations of the stomach arising from chronic catarrh, with success." Ewald also had demonstrated that percutaneous electricity increased the motor activity of the stomach, and since then he has used Einhorn's electrode, somewhat modified by himself, and in his work on "Diseases of the Stomach," page 69, he says:

"Surely by using Einhorn's stomach electrode, or my modification of it, contractions of the muscular fibers of the stomach themselves must be obtained, and, as I have already stated, and as I shall discuss later on, excellent results have been obtained, especially in gastric dilatation."

Again in 1892, in the Medical Record of January 30 and February 6, Einhorn publishes a paper entitled, "Therapeutic Results of Direct Electrization of the Stomach," in which he states that by means of his Deglutable Electrode he had been

able to treat a large number of patients. In this paper he reports the physiological effect obtained from both the faradic and galvanic currents, and also the therapeutic results obtained in a variety of stomach disorders. The physiological observations made and reported by him at this time were mainly on the power of electricity to increase or diminish the normal secretions of the stomach, and he concludes his observations by saying that direct faradism generally increased the HCl, and that galvanism—negative pole in the stomach—generally diminished this secretion. His conclusions are not in accord with some other observers; for Ziemssen finds that both currents increase the secretions of the various glands. The latter observer, however, made his experiments on animals.

On looking over the reports of the physiological effects, so carefully made and recorded by Einhorn, the amount of increase or decrease in the secretions is generally small and often inconstant; but in several cases in which the HCl was wholly wanting, he was able to find it in small quantities immediately after direct faradism; nevertheless, in these cases, even after prolonged treatment, HCl, was not found in the stomach after test-meals, showing that the stimulation to secrete HCl was not permanent. But in most all these cases there was a marked improvement in the patients' feelings, and their power of digestion, so that it is hardly probable that the benefit derived depends on either the increased or diminished secretion of the HCl. That Einhorn does not himself think that the improvement depends on this power of increasing or decreasing of the HCl is apparent, for he goes on to say: "Should we wish to utilize therapeutically these experimentally obtained conclusions, we would expect theoretically that the faradic current would be more advisable in cases of subacidity, whereas the galvanic current would be preferred in cases of hyperacidity. But in reality we shall see later on that this can not be made an axiom for therapeutics.

There were cases of hyperacidity which greatly improved by the faradic treatment, and, on the other hand, there were cases of subacidity in which the faradic current did not bring much benefit, and the galvanic current proved very useful.

Charles G. Stockton's statement of how electricity acts, although very indefinite, is, perhaps, as good as can be given. He says in the *American Journal of the Medical Sciences*, 1880, page 20:

"Exactly what rôle is played by faradism I am unable to state: whether it is a gastric sedative or a gastric stimulant, I do not know. My efforts were in the direction of study, and the results were so favorable that I applied faradism to cases seemingly contradictory in character, and I have concluded that the great variety of gastric neuroses depends upon a common cause—an imperfect innervation of the stomach: that electricity improves this innervation, thereby relieving the cause and so the conditions which, at first thought, are so contradictory."

But be the explanation what it may, certainly the therapeutic results as reported by Einhorn are sufficient to command attention. He reports marked success in cases of hyperacidity with dilatation, but by the use of the electricity alone he was not able to reduce the hyperacidity to any appreciable amount. He reports one case of gastrosuccorrhœa continua chonica cured by use of galvanism, in three months. Some of his most brilliant results were obtained in cases of severe gastralgia. In the treatment of these cases of stomach neurosis he frequently had success with the galvanic current (negative pole in the stomach) after failing to get good results with the faradic current. It will be noticed, however, that, though the pain was controlled and the patient became well so far as being able to eat without distress, yet there was little change noted in the degree of acidity of the stomach secretions. He summarizes the report of five cases as follows (February 6, 1892, MEDICAL RECORD, page 145):

"Although the five above-described cases are quite different from each other as regards the type of disease, they all, however, have one point in common, namely, a severe gastralgia which resists every kind of treatment; the gastralgia, however, is the symptom which chiefly troubles the patient, and, as time goes on, seriously endangers his subjective and objective welfare; in all these cases the constant current, applied to the stomach walls, brought much benefit, and this in quite a short time; the gastralgia succumbed to the influence of galvanization."

Again in his work on "Diseases of the Stomach," second edition, page 147, he says: "Gastro-galvanization is almost a sovereign means of combating severe and most obstinate gastralgias, no matter whether their origin is of a nervous nature or caused by a cicatrized ulcer of the stomach."

Since Einhorn's report of intragastric electrization by means of his deglutable electrode, several other authers have reported equally encouraging results. A. D. Rockwell in "Hare's Practical Therapeutics," second edition, vol. 1, page 304, says: "My own experience is that the appetite is sharpened, digestion is quickened and constipation is relieved by both general and local electrical treatment—so decided in many cases as to make it pretty evident that the gastric and intestinal glands are made to secrete more liberally by the action of the current upon the nerves that supply these organs, than on the tissues of these organs themselves." In the same chapter Rockwell says: "In my judgment electricity must be classed as a tonic of a very high order. . . . it gives passive exercise to muscles, it promotes and renders more natural the process of excretion and secretion; in a word, it imparts tone and strength to both nerve and muscles."

D. D. Stewart (in "Sarjous's Cyclopedia," vol. 6) finds direct faradism of value in chronic gastritis and stomach dilatations. But he did not see much benefit in cases of nervous belching by intragastric electrization.

Thomas G. Ashton writes ("Hare's Practical Therapeutics, second edition, vol. 2, page 409): "There now remains but little doubt as to the comparative value of direct gastric electrization over the so-called percutaneous method. By the latter method the current must be so diffused in its passage through the abdominal wall that it is doubtful if any portion of its effects arrive at the stomach, or at least these effects must be then so attenuated that but little good will result. Nevertheless, that some good follows the use of the percutaneous method has been demonstrated by many observers."

William G. Thompson writes in his "Practical Medicine," in the chapter on dilatation of the stomach, page 408. "The daily application of electricity is of decided benefit in some cases, but only when one electrode is inserted through a stomach tube, with a stomach partly filled with water, and the other applied over the epigastrium."

In the *Journal of the American Medical Association*, December 6, 1902, page 1444, J. Edward Stubbert, speaking of chronic gastritis as a complication of tuberculosis, says: "In such instances

all medication should be discontinued and a careful analysis of the contents of the stomach should be made after a test-breakfast. When hypochlorhydria exists this should be corrected. In the majority of instances, however, the most desirable method of treatment is stomach lavage about three times a week, and in cases in which dilatation exists, this should be followed by Einhorn's electrode."

Since October of 1901, I have been making personal use of intragastric electricity. My first patient on whom I used this treatment was a man about sixty-five years old, who had been suffering for some three months with frequent attacks of vomiting. I had been unable to control the vomiting except by keeping him under the influence of morphine. Having exhausted every resource, I made use of Einhorn's electrode, using the faradic current, negative pole in the stomach. After the second treatment the vomiting stopped. The treatment was continued about every third day for four weeks. Besides the vomiting he had suffered from pain after eating and had no appetite. The pains were greatly relieved and he had a good appetite under the treatment.

My success in this case encouraged me to make further use of this treatment in a limited number of chronic stomach troubles of various character. Of these I hope to make a report at some future time. My experience during these eighteen months taught me that I could not always introduce Einhorn's electrode, and for this reason I have had one made of my own design. It consists of, first, a red rubber tubing twenty inches long, about the size of a No. 13 (American scale) catheter. In one end is set a nut, around which is wound a fine wire, which runs through the rubber tube and is fastened to the slotted post in the other end of the tube; second, a screw with a flatted head goes through a hard rubber cap, shaped similarly to an elongated tablet, and smaller at one end than at the other. When the screw is fastened into the nut it holds the hard rubber cap in place, and the latter protects the stomach from direct contact with the metal. When it is desired to clean the electrode, unscrew the hard rubber cap by turning it to the left and press out the screw, and then all parts are easily cleaned. When the screw is in place, it prevents any fluid entering the tube. There is never any trouble in introducing this electrode, and the tubing being much smaller than the stomach syphon, it causes very little discomfort to the patient. Since the first few weeks, when I used Einhorn's electrode, I have made exclusive use of this one and have found it entirely satisfactory.

Einhorn's directions for using intragastric faradism are as follows: "Sitting ten minutes: at first large plate electrode at the gastric and epigastric region for five minutes, then a small ordinary sponge electrode. The electrode is at first moved up and down from left to right in the gastric region (sometimes, especially when there is constipation, the electrode is passed over the region of the colon—ascendens, transversum, descendens—always beginning in the right iliac region and stopping at the left iliac region [duration two minutes]; thereafter one proceeds from the gastric region from right to left to the back, and remains at the left side of the seventh dorsal vertebra for one minute. We then return to the front, moving the electrode gently up and down over the gastric region for two minutes, gradually decreasing the current and thus ending the sitting. The current has to be of such a strength that it causes distinct contractions of the abdominal walls."

His method of administering gastro-galvanism is very similar, using a current of 15 to 20 milliamperes.

In the treatment of gastralgia he uses the negative pole in the stomach, but Goldschmidt recommends that the positive pole be used internally.

In using intragastric electricity, I have modified Einhorn's method somewhat with apparent advantage.

I use a comparatively large sponge electrode, placed over the gastric region; and another small sponge electrode (connected to the same pole by means of a Y-shaped cord) is applied on the front sides of the neck over the course of the pneumogastric nerve, first on one side, then the other; thus the pole, used externally, has two terminal sponges. By using the small electrode over the pneumogastric increased stimulation of the stomach is experienced, as is noted by the greater contractions of this organ. As the pneumogastric has both motor and sensory fibers, it would appear that this would be a rational mode of treatment in both motor and sensory stomach disturbances. That there is greater motor stimulation I have demonstrated, but have not yet tested it in any case of gastralgia. I have also observed that this form of treatment had a sedative influence over the heart's action in one case.

In preparing patients for treatment they should be given first a glass of water, on an empty stomach; then the sponge electrodes and battery all should be in readiness, so that as soon as the electrode is introduced into the stomach the connections can be instantly made and the current started. In this way the patient does not have to retain the electrode one or two minutes before the treatment begins, and thus needlessly prolong the sitting, and, furthermore, the inclination to retch is not nearly so great when the current is on.

The primary current may be used in the more chronic cases, but the secondary, long coil, is better suited when a sedative influence is desired.

The primary or low-tension current of the faradic battery (when either pole is used internally) has a greater power for exciting contractions than the secondary current, so the former would be used when such action is desired, as in cases of stomach dilatation, when there is no pyloric obstruction.

During the treatment, patients experience a pleasing warm sensation in the stomach, and after the treatment they express themselves as feeling rested.

In conclusion, I may say that intragastric electrization would not be resorted to except in those cases that had failed to yield to medicinal and dietetic treatment, but when these have failed it will be found of inestimable value.

---

**Missing Links in Joint Disease.**—Preston King believes that evidence points strongly to the fact that rheumatoid arthritis is not a distinct disease due to any one specific organism, and that it is a condition of ill health resulting from various infective poisons. Indeed, the evidence to be found in the previous history, the exciting causes, the clinical features, and the bacteriology of rheumatoid arthritis all point away from this being any longer recognized as a distinct disease. It is a condition due, not to any one specific germ, but to various different kind of germs, which link it to rheumatism, to rheumatic arthritis, to gout, and to other diseases. The writer suggests that these organic poisons, either by themselves or through their toxins, produce their results by acting through the nervous centers in an individual whose vitality is lowered and whose joints have a tendency to disease.—*The Bristol Medico-Chirurgical Journal.*

# A CONTRIBUTION TO THE STUDY OF THE INTERCOSTAL PHONATION PHENOMENON AND THE LITTEN DIAPHRAGM PHENOMENON.

By ALBERT ABRAMS, A.M., M.D.,
SAN FRANCISCO.

DIAGNOSIS is made up of such a multitude of little things, that nothing, however insignificant, can be ignored. This refers with all cogency to the diagnosis of chest diseases, for, notwithstanding our vaunted progress in the diagnosis of such affections, our conventional methods, notwithstanding their faithful execution, leave much to be desired. A recent method of diagnosis suggested by Stiller, the *intercostal phonation phenomenon*, is observed in lean individuals. It consists of a distinct elevation of the intercostal spaces when short words or syllables are uttered by the patient. The wider the intercostal spaces, and the latter are widest between the axillary and parasternal lines, the more evident the phenomenon. The phenomenon is specially distinct where the respiratory excursions of the lungs are greatest, viz., in the lower thorax. Weiz first described the phenomenon in question, but his explanation of its genesis was incorrect. It is caused by waves of air, which in the moment of phonation when the glottis is narrowed, are carried in all directions down the bronchial tree to the region of the lung contiguous to the intercostal spaces, causing these to bulge. The pressure is also exerted on the relaxed diaphragm, causing it momentarily to descend, which descension is manifested by slight protrusion of the epigastric angle, which may be observed even in obese individuals. In individuals in whom the bulging is not clearly manifest, the phenomenon may be detected by palpation. The practical value of this phenomenon in diagnosis, as suggested by Stiller, is the ability to determine the boundary between the lung and the liver or spleen and to recognize the existence of a pleural ex- or transudate and to differentiate the latter from a pulmonary infiltration or lung tumor if this is necessary. If fluid is present in the pleural space, the sudden increased pressure in the lung during phonation excites in the contiguous fluid push waves, which bulge the intercostal spaces: thus the dulness of a pleural exudate can be differentiated from the dulness caused by lung infiltration or tumor of the lung. This phenomenon also permits of an accurate demarcation of the liver or spleen from the fluid in the pleural cavity. The writer has carefully studied the phonation phenomenon in a large number of cases, and he finds that it is best elicited, if during phonation the patient closes his nostrils and places his other hand over his mouth, so that the expired air is partially obstructed in its exit from the lungs. Again, the patient should be instructed to practise forced expiration before phonation is attempted. For determining the line of demarcation between the lung and the liver or the lung and the spleen, the phonation phenomenon can never substitute careful percussion. Its real value lies in differentiating lung infiltrations from accumulations in the pleural cavity, and even here one can not regard the phenomenon as infallible, insomuch as it cannot be determined in obese persons, when the exudate is so large that it compresses the lung or when pleural thickening and adhesions exist.

THE LITTEN PHENOMENON.—This procedure, suggested by Litten[2] in 1892, renders visible the diaphragmatic movements. The most detailed description of this maneuver may be found in the admirable textbook of Cabot[3] and in the third edition of Sahli.[4] To elicit the Litten phenomenon, or phrenic shadow as it is also called, the patient lies upon his back with exposed chest and the feet directed toward a window. Cross lights must be eliminated by darkening other windows in the room. If the patient's bed cannot be placed in proper position with relation to the window, or if the observation is to be made at night, Cabot suggests using a strong light held at the foot of the bed, excluding all other lights.

The observer stands at the patient's side, as shown in the illustration, or stands a few feet from

Fig. 1.—Litten's diaphragm shadow. Proper position of patient and observer. The shadow is best seen near L. (Cabot.)

the patient with his back to the window and observes the lower chest at an angle of 45°. The observer then directs the patient to take a deep breath, and as the ribs rise with each inspiration, a short narrow shadow moves along the axilla from about the seventh to about the ninth or tenth rib. The shadow is less evident during expiration as it ascends to the point from which it started. In ordinary breathing, the shadow in its descent occupies 1–1½, and in forced inspiration, 2–3 intercostal spaces. The shadow line cuts the ribs at an oblique angle. The phrenic shadow can be observed on both sides of the chest and not infrequently in the epigastrium. It is best observed in lean individuals of either sex, and is never absent in health unless the individual is very obese or cannot be made to take deep breaths. In normal persons, during ordinary breathing, the shadow excursion is about 2½ inches; whereas in forced breathing it is 3½ inches. The diaphragm phenomenon is easily explained, if reference is made to the accompanying figure. At the end of expiration, the diaphragm lies flat against

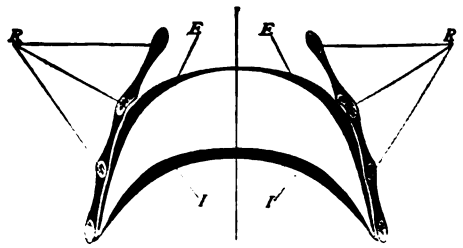

Fig. 2.—Excursion of the diaphragm during forced respiration. R, ribs; E, position of the diaphragm at end of expiration; I, position of diaphragm at end of inspiration. (Cabot.)

the chest from its attachment up to about the sixth rib, but during inspiration, it "peels off" as it descends and permits of the lung edge to come down into the space between the diaphragm and the chest wall. The "peeling off" of the midriff and the descent of the lung during the inspiration causes the moving shadow. The phrenic shadow is of undoubted clinical value and enables us to dispense with the Röntgen rays in many of our examinations.

First of all, the phrenic shadow permits us to say that in that particular chest region the diaphragm and the lung lie in contact with the thoracic wall, and that both are freely movable. Its absence would suggest an opposite condition of things. In pneumonia of the lower lobe, pleural effusion, pneumothorax and pleural adhesions, no shadow can be obtained. In all the preceding conditions the diaphragm is displaced from the chest wall, so that its excursions communicate no shadow. In advanced emphysema the shadow is diminished or lost, and the prognosis in this affection is gauged almost as effectually by the excursions of the shadow as by the spirometer, and the epigrammatic utterance of Lermoyez[5] seems apposite, that, in emphysema, "the ear makes the diagnosis, but the spirometer makes the prognosis." In the differential diagnosis, between empyema and a subphrenic abscess, the presence or absence of the phrenic shadow may be of service; in the former condition it is absent, in the latter it is present, however feebly expressed. Partial adhesions between the diaphragm and the chest wall are often recognized by an irregularity in the otherwise straight shadow. It has also been suggested that the phrenic shadow may be enlisted in differentiating a pneumothorax from a diaphragmatic hernia. The shadow is also of undoubted service in gauging the progress toward recovery of certain affections of the respiratory apparatus. In phthisis all writers are now agreed that limited diaphragmatic excursions constitute one of the earliest signs of the disease. It was Williams[6] of Boston who was probably the first to give prominence to this sign. To the knowledge of the writer, no explanation has been adduced in explanation of such limitation in the movements of the diaphragm, and he has shown elsewhere[7] that the condition is associated with hyperdistension of the lung, which, practically speaking, is nought else but a lung emphysema. Clinicians have long recognized, notably West,[8] that in certain general diseases in which the lungs are not otherwise affected, there is a loss of tone or tension in both lungs. The condition, has been comparable to tympanites. The term pneumoparesis is not applicable to the condition, as it implies an involvement of the vasomotor-nerves. The aufblähung of the Germans or *Volumen pulmonum auctum* is more suggestive of the lung condition. All this, however, is a mere theoretic discussion of the condition of the lungs in phthisis, for the clinical picture tallies in the main with that of emphysema. The following conclusions may be formulated as the result of the writer's observations with reference to the early phthisical lung: (1) In health the percussion note of the lungs is resonant during inspiration, and dull or even flat during forced expiration. (2) In phthisis, in the uninvolved lung areas and in a lung susceptible to tuberculous infection, the percussion note is unchanged during the two phases of respiration. (3) Associated with this unchanged percussion sound, there is an extension of the lung borders manifested by downward dislocation of the lung and diminution often to the extent of obliteration of the cardiac and splenic areas of absolute dulness. (4) Hyperresonance and not dulness is characteristic of early phthisis or of lungs predisposed to the disease. (5) The Röntgen rays show that while the diseased portion of the lung may be darker than normal, the unaffected areas show diminished density. (6) The diaphragm is restricted in its excursions in individuals predisposed to tuberculosis, whereas in phthisis it is markedly restricted on the affected side or sides, specially in the lower part of its excursion. Summarizing our knowledge of the move-

SYNOPTIC TABLE OF THE PHRENIC SHADOWS.

| PHRENIC SHADOW. | DISEASES OF THE LUNGS. | DISEASES OF THE PLEURA. | DISEASES OF THE DIAPHRAGM. | GENERAL DISEASES. |
|---|---|---|---|---|
| Is diminished. | 1. Bronchitis (usually on both sides).<br>2. Emphysema (both sides).<br>3. Tuberculosis on both sides, specially affected side.<br>4. Abscess of lung (on affected side.<br>5. Asthma (interparoxysmal period).<br>6. Atelectasis.<br>7. Bronchopneumonia.<br>8. Lung congestion. | 1. Pleuritic adhesions on affected side and the shadow is irregular.<br>2. Pleuritis (on the affected side). | 1. Subphrenic abscess. | Myogenic causes:<br>1. Debility.<br>2. Anæmia.<br>Mechanic causes:<br>1. Pericardial effusion.<br>2. Cardiac enlargement.<br>3. Pregnancy.<br>4. Ascites.<br>5. Distension of stomach or intestines.<br>6. Abdominal growths.<br>7. Enlargement of liver.<br>Inhibitory causes:<br>1. Peritonitis.<br>2. Pericarditis (acute). |
| It is absent. | 1. Pneumonia (on affected side).<br>2. Advanced emphysema.<br>3. Asthma (during paroxysm) | 1. Hydrothorax.<br>2. Pneumothorax.<br>3. Empyema.<br>4. Pleural thickening.<br>5. Pleuritic adhesions. (extensive).<br>6. Diaphragmatic pleuritis. | 1. Spasm of diaphragm.<br>2. Paralysis of the diaphragm. | In the foregoing conditions when pronounced. |
| It is increased. | On the unaffected side when, in consequence of disease, there is difficulty in respiration, the increased shadow is then purely complementary or compensatory. | | | |

ments of the diaphragm as influenced pathologically, and determined by the phrenic shadow, the above table is submitted.

It must be conceded that careful percussion affords in most instances a trustworthy gauge of lung mobility, but in every instance, all things being equal, the eye is a more reliable guide than the ear. An ocular demonstration of the phrenic shadow constitutes one of the most picturesque signs in clinical medicine. One reason why the phrenic shadow has not been brought more frequently into use is on account of the inconvenience necessary for its elicitation. The writer employs the sign constantly in diffuse daylight without special reference to the position of the patient. Used after this manner, it offers none of the inconveniences of the conventional clinical method. It is true that the uninitiated may, at first, experience some difficulty in its elicitation after this manner, yet, when once mastered, its recognition is easy. If the patient is in bed, it is more convenient to pursue the conventional method, but if the patient is an ambulatory one, he is placed with his back to the window, while the observer is seated at his side as depicted in the illustration. The patient stands with arm extended above the head, while the other arm supports the side. The position of the observer is not constant, and it may be necessary for him to view the axil-

lary region at different angles. The patient is then instructed to practise forced inspiration, but this exaction is often more difficult than the actual demonstration of the shadow. If he will not take a deep breath, ask him to cough or to suspend respiration for a time, or even make some violent exertion, maneuvers which will bring into play augmented midriff action. If the shadow is recognized, it may be followed to a surprising distance around the chest, and this fact alone suggests the advantage of viewing it in diffuse light. It is better, however, that those who have never seen the phenomenon should seek for it after the conventional manner, and then attempt its elicitation after the method here recorded. Another advantage of demonstrating the shadow in diffuse daylight, is evidenced by the fact that it can be seen on both sides at the same time, so that any discrepancy in the shadow becomes at once manifest. The patient stands as before, with his back to the window, while the observer sits a few steps away with his back also to the window. The patient, now being instructed to practise forced inspiration, the observer notes a punctated retraction of the lower thorax (marked by crosses) on either side, beginning usually in the scapular line, but not infrequently in the posterior axillary line, followed by a shadow which descends and ascends in the intercostal spaces. Note in the illustration that the patient's arms are extended above the head and the body is inclined slightly backward, as if to relax the muscles of the back. This mode of attitude is necessary to obtain the best results. The writer has sought to exaggerate the shadow by different means, and he finds that if the skin is colored yellow over the area described by the excursions of the diaphragm, the shadow picture is much intensified. For this purpose the skin may be colored with picric acid solution, or, better still, a saturated alcoholic solution of gamboge may be used, as it is readily removed by means of alcohol. If neither of these agents is at command, anointing the skin with yellow vaselin will suffice. This coloring of the skin will also intensify the shadow when the conventional Litten method is executed.* In concluding our examination after the manner just cited, we must not be unmindful of the fact that the phrenic shadow can be confounded with two other manifestations, which likewise produce shadows, viz., the expiratory sinking of the lower ribs and the inspiratory retraction of the lower intercostal spaces. The former is an expiratory, whereas the phrenic shadow is an inspiratory depression. Inspiratory retraction of the intercostal spaces is more likely to be confused with the phrenic shadow. In the former, however, the shadow is diffuse, whereas in the latter it is linear and the line can be seen to descend during inspiration to ascend again during expiration.

*Since the foregoing investigations were made, the writer has found that if the skin embracing the area of the chest to be observed is made taut by grasping a fold of the skin, an intensification of the phrenic shadow results to a degree almost as great as when the skin is colored. Care must be exercised in not drawing the skin too tight, for otherwise respiration will become embarrassed and the shadow correspondingly diminished.

## SOME DANGERS OF THE HOT-WATER BOTTLE AS APPLIED TO THE NEW-BORN.

By DOUGLAS H. STEWART, M.D.,
NEW YORK.

ANY defence of the time-honored hot-water bag is unnecessary. There is so much of good and so little of evil in its influence that its pernicious powers seem to have been lost to sight and memory. To its modicum of harm attention is invited.

How often is a feeble neonatus placed on an uncovered hot-water bag and burnt! Even after the burn is healing an eclampsia sets in, lasts a variable length of time and is followed by death. Such a burn may be so pitiably trivial that its effect on the convulsions may be quite overlooked; yet when situated on the buttocks, the lower back, the occiput, or near the navel, it is a most likely forerunner of fatal convulsive attacks. On the other hand, I have not seen a single instance of such eclamptic seizures following burns of shoulder, arm, leg, or thorax.

It certainly can do no harm to strip every infant in every case of convulsions, yet many obstetricians rarely see a baby's back after the handling of actual delivery. Talcum powder, silence, and manipulation may so completely hide all evidence of an accident caused by the nurse's carelessness in the application of heat, that although the doctor may closely examine the navel the infant may be lying upon a septic burn, and the true cause of "spasms" may not be apparent. From the above one might gather the idea that the injury described is common. I think it is. It is discovery that is rare.

Intracranial hemorrhage may follow overheating and extensive burning. One of my little patients was an instance of *post hoc*. He had given no sign of cerebral trouble until the buttocks and back were damaged by contact with a large hot-water bag. Autopsies show cerebral congestion and various capillary embolisms in the bodies of persons dead from the traumatisms of heat. In the new-born the convulsions, nystagmus and all that are symptoms common to burns and cerebral hemorrhage; and, in my single case, the fontanelle began to bulge some thirty hours after the burns.

If the reader will examine every new-born child on the third, sixth, and ninth days after birth he will become just as timid as I am, and will soon be as vigilantly watchful that there is always a thick folded blanket above every hot bag (not necessarily hot-water bag, for the material may be shot, sand, towels, etc.), and for that matter, a thick folded towel under every ice-bag.

An interesting case with autopsy is quoted in Quain's Dictionary:

A girl, aged fourteen, was covered with a sheepskin, and loaves of bread fresh from the oven were packed around her. She went to sleep and died. Similar loaves showed a temperature of 185° F. I have found temperatures varying from 120° to 200° in hot-water bags just taken haphazard with an ordinary bath thermometer, and the child that would have been laid on them was scarcely as many minutes old as the girl above mentioned was years.

A danger, which is most likely to happen when glass bottles are in use, is heating of the carotids. Although the evil effect of this action is well known to physiologists, it appears to have been overlooked by practitioners. Nowadays intravenous injections at 120° are common, thus one might forget that keeping the blood in the carotids at 110° or over may be followed by death.

In the use of the hot intravascular injection there

are at least three mitigators: (1) sodium chloride; (2) the body's heat-regulating apparatus, and (3) the transient duration of the temperature (120°).

Sodium chloride raises the coagulating point of albumin solutions, *e. g.* serum albumin in pure solution may be coagulated at 50° (122 F.), but the addition of NaCl. raises the temperature required for coagulation to 75°, or even to 80° (167° and 176° F.).

When a hot injection is made into a vein of the forearm, there is a constant unchecked radiation from the apparatus employed, and furthermore the patient's heat-regulating mechanism has some opportunity to modify the warmth before the blood is sent through the internal carotids and vertebrals. If, however, the temperature of the internal carotids is raised and maintained by contact heat, these vessels having no branches in the neck, the heat is conveyed into the cranium, through the circle of Willis, and simultaneous elevation in the vertebrals should render the effect, on the medulla and respiratory center, direct and marked.

The following from "Foster's Physiology" may prove interesting (I change some sentences for brevity's sake): "If the blood in the carotid be warmed above normal, dyspnœa is produced. It is not identical with that caused by imperfect arterialization of the blood, but it shows that the too high temperature of the blood directly affects the activity of the respiratory center." And again, "the regulative heat mechanism is unable to withstand the strain of too great an external heat or too prolonged an exposure to a less degree." Too warm blood exhausts the metabolic capital of the respiratory center, and it hurries on the beats of the heart, each stroke becomes more and more feeble as the rate is quickened, the beats become irregular, and finally cease. "Either of these two events alone, and certainly both together, are enough to bring mechanism to an end."

Ralliere demonstrated (dogs) that the blood temperature may be increased to 107° F., or (temporarily) even to 109.2° F. if immediate cooling is allowed. He states very plainly "The danger of hyperthermy lies in the duration." Now we can raise the temperature of the contents of the internal carotids above these figures by direct heat which may be maintained more or less indefinitely. But to return to our Medical Physics and ignoring all the nervous mechanisms of the body. Given a person weighing 143 pounds, whose blood weighs 13 pounds, and has a temperature of 100°, what will be its temperature if 6 pounds of salt water at 120° be mixed with the blood? The mixing to be instantaneous.

6 pounds @ 120° = 720 heat units.
13 pounds @ 100° = 1,300 heat units.

19 pounds @ × = 2,020 heat units.
2,020 ÷ 19 = $106\frac{6}{19}$ heat units per pound.

Ergo. $106\frac{6}{19}$° is all that could be obtained in a pail.

In the body we probably never do obtain this, because of the fact that in practice we begin with our fluid at 120° and take thirty minutes to inject it, during which time the laws of radiation are not in abeyance. We can hardly take it for granted that a bodily system which enables men to work in atmospheric temperatures of over 120° will remain inert when that same temperature is introduced into the vessels. On the contrary, with any duration of heat, not sufficient to overthrow the mechanism, would it not be quicker in its regulating action upon intravascular excess.

A perfectly healthy new-born child was placed in his crib, a hot-water bag underneath him and a bottle filled with hot water each side of his neck. This was the nurses' precaution, as the room was not very warm. She knew how efficient an ice-bag was when applied to the vessels of the neck, and she supposed heat could be utilized in the same manner with good effect. At the end of about a half-hour, on uncovering the child, I was surprised to find it breathing in a most peculiar manner similar to the Cheyne-Stokes' respiration. This soon ceased after picking up the infant, but, a few days later, I saw the same sort of dyspnœa in an older child; only here it followed a long continued poulticing of the neck. The rectal temperature was 104.2°. The poultices were discontinued, and all bad symptoms had disappeared at the time of my second visit, *i. e.* about two hours after the removal of the poultices.

One reason that such occurrences are not found frequently, is that the rubber hot-bag does not readily fit into the neck, but bottles will roll, and will stay snugly against the skin over the vessels of the neck. In my case, as the bottles formed an arch, their tops being in contact, any question of antero-posterior pressure may be dismissed. As to the temperature, I should say that any degree or amount of contact heat sufficient to keep the temperature in the carotids at 110° or over will certainly produce the disturbances described in about thirty minutes.

NOTE.—Since writing the above I have transfused two liters of decinormal salt-solution with a maximum of 120° and a minimum of 116° F. Observations of the rectal temperature during the time the solution was running into the arm showed 99½°. Five minutes after the transfusion was completed the rectal temperature was unchanged. This demonstrates that no parallel can be drawn between the application of direct heat and heat as used in intravenous transfusion.

## ARTIFICIAL FLUORESCENCE OF LIVING HUMAN TISSUE.

BY WILLIAM JAMES MORTON, M.D.,
NEW YORK.

As is well known, the *x* and similar radiations produce a coloration of many salts in solution. Upon this quality is based radiography. These radiations also cause certain dry crystalline and other substances to fluoresce and phosporesce. And upon this quality is based radiofluoroscopy and the fluoroscope in common use. *X* and other radiations also cause fluorescence and phosphorescence of quite a number of salts and chemical substances when these are held in solution. This latter fact may be easily demonstrated by the following simple experiment: Dissolve in a test-tube five grains of bisulphate of quinine in, say, three drachms of water. Close, for convenience, the test-tube with a cork and place it in the ordinary fluoroscope box from which the usual fluoroscopic screen has been removed and replaced by a covering of several layers of black paper. Upon now exposing the test-tube to the *x*-ray the solution of quinine will be seen to glow with a fine opalescent, bluish-purple fluorescence. The same experiment may be made with various other sustances, each affording a characteristic fluorescence.

Calculating the amount of blood in a human body to be one-thirteenth part in weight of the entire body, we may estimate that a person weighing 130 pounds will contain ten pounds of blood. This is equivalent to ten pints, or

equivalent to one grain to eight ounces of water. We may, therefore, without doubt, conclude that the fluids of a person to whom twenty grains of quinine has been administered represent a solution of quinine equivalent to that above mentioned; and equally when such a person is exposed to the *x*-ray, that the person's tissue will be rendered fluorescent in the same manner.

Among fluorescent liquids, some of which may be used medically, Mr. W. J. Hammer, in a recent publication, enumerates the following: petroleum, quinine, Magdala red, eosine, uranine, saffronine, paviine, aesculine, amidophthalic acid, fluorescine, rhodamin, thalleen, resorcorufin, and resorcin blue.

In the treatment of cancer and other diseases it occurred to me that I possibly might avail myself of these facts to administer a drug medically, capable of fluorescence and at the same time establish its fluorescence in the tissues themselves by means of the *x*-ray. In the case of the quinine solution we should get the much desired violet radiation, and get it, too, in very close quarters with the tissue elements we desire to effect. A feeble fluorescence of a quinine atom lying against a tissue atom should equal in therapeutic result a much more powerful radiation from a fluorescing source much further distant. Acting upon this idea I have been in the habit, during the last year, of administering from five to ten grains or more of bisulphate of quinine about one hour before *x*-ray treatments. I cannot affirm it, for we have nothing thus far but clinical evidence to rely upon, but I believe that my cases thus treated by a combination of fluorescing medicines and the *x*-ray have made more improvement and more certain recoveries than patients not thus treated.

At all events, while all are so blindly groping in the treatment of cancer, the idea involved in the procedure I have ventured to term *x*-ray histofluorescence has seemed to me worthy of submitting to others for trial and investigation.

I have also employed this combined treatment of the *x*-ray and internal administration of fluorescing medicines to advantage, in cases of chronic malaria, Hodgkin's disease, lupus, tuberculosis, and tuberculous deposits, and, in short, whenever it is desirable to set up reparative tissue changes, important to accomplish *per se* or as resistance to bacterial and parasitic invasion. A solution of quinine may also be used hypodermically and locally if desired, or may be applied with a brush upon an exposed or denuded surface. Any portion of the human body thus artificially fluorescent may be photographed in a dark room by its own light, and I have already obtained several such photographs.

**Some Points in the Diagnosis of Gout and Some Aberrant Forms of the Disease.**—H. W. Syers says that it must be admitted that there is a use for the word "gouty" in the sense that certain symptoms depend upon the gouty constitution. It must never be forgotten that the changes external to the joint in gout may be quite as marked as, or even more so than, those which are internal to the articular cavity. It is not sufficiently recognized that the gouty process may set up an overgrowth of the bony tissue surrounding and immediately adjacent to the articular surface, while the latter is almost free from morbid change. As to latent gout, the patients who are affected in this manner are those who possess a marked gouty inheritance. Most characteristic of latent gout, though often misinterpreted, are the gastrointestinal symptoms from which this class of patients so often suffer. The most usual of these symptoms is acid dyspepsia. Great aggravation of symptoms ensues from the habit of smoking. The tendency to acidity is always accompanied with flatulence. Perhaps the most inconvenient of all these digestive troubles is a tendency to diarrhœa. It comes on at any time and is imperious. Apart from this annoyance, patients are generally quite free from any ailment whatever so long as they observe ordinary caution in regard to diet. The greatest care should be given to the diet. But no matter how much care and trouble are taken, the tendency to irregular action of the bowels will not be altogether overcome. It is an effort of nature to rid the system of noxious matters. There is no fear of an acute attack so long as this tendency to looseness of the bowels exists. The quantity and quality of nitrogenous food must be carefully regulated, but it cannot be cut off entirely. Short and repeated courses of carbonated water will often be attended with very good results.—*Treatment.*

**Hysterical Affections of the Eye.**—H. Gradle declares that with the exception of absolute hysterical blindness he has met with functional derangements attributable to hysteria so often that they constitute a notable percentage of the average practice. Of hysterical blindness, there are some fifty cases reported. The objective examination alone does not permit the distinction between hysteria and simulation. This origin may be suggested by the history. The only absolute proof of hysterical origin is the possibility of restoring the sight by psychic influence. A singular phenomenon in hysterical amblyopia has been recorded under the name "tubular field of vision." When there is a constriction of the field, the absolute area of the field is the same, no matter at what distance it is measured. The patient sees the world as if looking through a tube of infinite length. Double sight with one eye, not accounted for by optic conditions, is a symptom very suggestive of hysteria. Far more frequent than visual disturbances are pains and disagreeable sensations localized in the eyes or radiating from them into the head. But it is proven only when we succeeded in dispelling the discomfort by purely mental therapeutics—for instance, electricity. The most frequent hysterical motor phenomenon is winking. Irregular action of the ciliary muscles is an occasional manifestation of hysteria. It can usually be relieved by proper glasses, but may require some mental therapeutics.—*The Chicago Medical Recorder.*

**The Etiology of Serofibrinous Pleurisy with Reference to Cytological Diagnosis.**—C. H. Bunting says that, from his study of pleurisy cases, he does not pretend to show that all idiopathic pleurisies are tuberculous. That can be shown only by a large series of animal inoculations. These cases have, however, an exudate remarkably uniform in cellular content and general characters, which may be assumed to indicate a uniformity in the nature and etiology of the process. This uniform cellular formula, the work of others seems to indicate, is the formula of tuberculous pleurisy. Clinically considered, the cases of primary pleurisy studied may be divided into two groups: The larger group includes those which may be termed insidious pleuritis. The onset is more or less acute, but there is very little fever. The exudate is practically a chronic one when aspiration is made. The smaller group includes the cases in which the attack sets in with marked fever and such severe general symptoms that the patient is forced to take to his bed at onset. The cellular formula shows no distinction between these groups of cases. Aspiration has had no effect on the fever. The red blood count was uniformly high. A single case has come to autopsy. Tubercle bacilli had not been demonstrable in the sputum, nor had there been intrapulmonary signs. At the postmortem almost complete obliteration of both pleural cavities was found and also marked tuberculous involvement of the lungs.—*Bulletin of the Johns Hopkins Hospital.*

## THE POSSIBLE NATURE AND LIFE CYCLE OF THE YELLOW-FEVER GERM.

SOME interesting and ingenious speculations on this subject, especially interesting as showing what some can get out of facts long and well known, are given by Dr. Carlos Finlay, Chief Sanitary Officer of Cuba, in the *Revista de Medicina Tropical*, for April, 1903. Starting from the difference in the duration of the clinical course of yellow fever and malaria, the author argues that whereas the human is the permanent host for the malarial plasmode, the mosquito (*Stegomyia*) is, on the other hand, the permanent host for the microorganism of yellow fever. And that while the reproductive stage of the malarial plasmode is passed in the mosquito (*Anopheles*) the reproductive stage of the yellow-fever microorganism is passed through in man. Regarding its nature, though it may seem idle to speculate about a thing that we have never seen, nevertheless the general similarities of all its manifestations suggest strongly that it is similar to the malarial plasmode—that is, that it, too, is a protozoan parasite. Thus we know that, like the malarial plasmode, it requires two hosts to complete its cycle, and one of these hosts is a mosquito (*Stegomyia*). Now remembering the facts of the development of the malarial plasmode—that the embryos leave the salivary glands of the mosquito to enter the body of a non-immune host, there grow to adult age, multiplying by schizogonia or sporulation in the blood, and continue to do so long after they have become ripe for sexual reproduction, sporulation recurring at regular intervals, and evoking the regular recurring chills which last sometimes several months where not treated—we see that this tenacity of existence in man clearly proves that he is the permanent host for this parasite. But sexual reproduction never takes place in the human, it occurring only in the body of anopheles. Should the latter not appear on time, resting bodies (crescents) are formed, which continue indefinitely the life of the parasite in the human body (though without the production of symptoms) until such time as opportunity arises for the parasite to reach the mosquito. When it does reach that host sexual reproduction results in the production of a large number of embryos which find their way into the salivary glands ready for immigration into a new, non-immune, permanent host. Should no such host appear, however, the embryos die, either in the salivary glands of the insect, or on infertile soil where they may happen to have been deposited. Again anopheles will become infected by stinging a malarial subject at any time when the parasite (in the form of resting bodies) is in the peripheral blood, a condition which lasts several months; while we know that stegomyia can be infected from a yellow-fever patient only during the first few days of the attack, the infection of convalescents not being transmitted to a new abode to which they may remove. While we do not know the utmost length of time that the malarial embryos may live in the salivary glands of anopheles, that time must, nevertheless, be comparatively short, as for want of space and nourishment in the tiny body of the mosquito they will not be able to reach their full development. We know positively, however, that the yellow-fever germ can live in stegomyia at least two months (and, in all probability, till the death of the mosquito). How explain this difference? Being the parasite of a minute insect, one would naturally expect that the yellow-fever germ would be much more minute than the malarial germ which has at its disposal, for food supply, the human body. Recalling the difficulty with which the first investigators recognized the malarial sporozoites in the salivary glands of anopheles, the search for yellow-fever sporozoites in the human may well be a hopeless undertaking. Possibly, however, some larger resting form might be found in infected stegomyias, and its discovery may be assisted by the consideration that it is here that it is to be looked for, and not in the blood of yellow-fever patients. Finally it is to be remembered that the actual existence of ultra microscopic germs having now been demonstrated, it is possible that the yellow-fever germ falls into this category. When we remember the small amount of food that a mosquito could supply to a great number of germs, one is inclined to suppose the relation between host and parasite to be one of commensals—that is, that the parasite takes part of the food in the mosquito's alimentary canal, as do many intestinal worms in man. In this way might be explained the association of infection with bacteria, which might possibly serve as extemporaneous hosts for the infra-microscopic germs.

Finally, the author adds that, from the prophylactic standpoint, over and above the attempt to exterminate the intermediate host, the foregoing considerations emphasize the importance of the prevention of infection of that host. As regards malaria, unfortunately, such prevention is practically impossible, by reason of the length of the life period of the parasite within the human body; but it is comparatively easy to prevent the infection of healthy stegomyias by yellow-fever patients.

## PROSPECTS IN THE MEDICAL PROFESSION IN GREAT BRITAIN.

THE plaint of the doctor in this country is a bitter one. It is asserted that it is with difficulty the ordinary medical practitioner is able to make a bare living. When, however, it is considered that there are in the United States 156 schools of medicine, and that the estimate has been made that there is an average of one physician to every 600 of the population a ready explanation is given of the dearth of "loaves and fishes," for the individual members of the medical profession. It is simply a question of the supply being greater than the demand.

In Great Britain the prospects of a doctor are not especially bright, but according to an exceptionally able article which appeared in *Cornhill Magazine*, June, they would seem at least to be better than in this country. The article referred to is written anonymously, but by one who knows well whereof he speaks. The medical profession in Great Britain is described as being a career suitable to a man whose ambition is not solely to make money, and who likes a hard-working earnest life. It is a profession access to which is not over-expensive, and one in which it is always possible to secure a subsistence from the outset. But are no great prizes to be obtained in medicine as there are in the church the law, engineering, or army, or are there no well-paid sinecures into which the medical man, wearied with a life of toil and strain, may gently fall and end his days in luxury and peace? The life throughout is strenuous and full, but on the whole one to be desired by an energetic, independent man.

The following is the account given in *Cornhill Magazine* of the various ways of entering the medical profession in Great Britain: "The control of legal admission to the profession is shared between the twelve universities and the nine professional corporations of England, Scotland, and Ireland, and a 'General Medical Council' which is mainly constituted of their representatives. To obtain admission to the 'Medical Register,' or roll of the profession, which is kept by the General Medical Council—that is to say, to become a legally qualified medical practitioner—it is necessary to obtain a degree or diploma, or a combination of several implying proficiency in the three branches of medicine, surgery, and midwifery.

"Degrees in medicine and surgery can only be obtained from the universities: diplomas possessing equal legal validity are granted by the corporations, which are partly linked in each division of the kingdom, for the purpose of granting qualifications in complete form."

The time required in medical study is a minimum of five years, but the five years is but a minimum. The majority who go in for a diploma do not qualify within this time, while for a degree at an English university, it is safe to reckon upon a course of six or seven years. The cost of a medical education in Great Britain varies very considerably at the different schools. Examination fees run all the way from $75 to $310. At the best London schools the curriculum for the college diplomas costs about $800, that for the London university degree about $950. The charges in Scotland and Ireland and in the provincial schools are less.

When a man has succeeded in taking his diploma or degree in medicine in Great Britain, he may embark in general practice, enter one of the public services, or qualify himself for consulting work. Taking into consideration the difference in the country and people, general practice in Great Britain and here is much alike. The work is laborious—more laborious of course in the United States than on the other side—and ill-paid. The average income, however, is better in England than in this country.

The manner of entering practice in Great Britain differs widely from the mode pursued in this country. according to the article above mentioned, "The 'good-will' of an established practice is a valuable asset, and may be acquired either through a partnership, or purchased outright from a retiring practitioner, or from the heirs of one lately deceased. The price to be paid varies according to circumstances, but in general may be stated at from one to two years' gross income of a practice or portion of a practice purchased."

A capital sketch is given of the inducements offered to young medical men to enter the British services, but our space is too limited to more than say that they present to a young man without capital a most promising career. The Indian Medical Service is even better than the army or navy, so far as pay is concerned. It goes without saying that the highest prizes of the British medical profession, as in all civilized countries, falls to the lot of the consultants. For this class London is the most lucrative field, although Edinburgh runs it hard, while many of the large provincial cities like Manchester and Liverpool afford ample scope for the exercise of the abilities of the talented, able man, with the promise of rich pecuniary returns.

The average fees of a doctor here are larger than in Great Britain, but owing to the overstocked condition of the medical profession in the United States, the average yearly earnings of medical men are larger in the United Kingdom than in this country.

---

## WHAT CONSTITUTES DEATH AND WHEN DOES IT OCCUR?

HERBERT SPENCER, it will be remembered, has defined life as a continued adjustment of internal relations to external relations, and it is doubtful whether any definition of death would be better than a rupture of that adjustment. Ordinarily, of course, every one thinks that he knows when a man is dead. But when looked at more closely the subject is not quite so simple. For example, shall we say that a patient is "dead" when respiration ceases? In the writer's experience a woman suddenly became unconscious and ceased all attempts (even the slightest) at respiration. Under artificial respiration, however, the heart beat for five hours, when the artificial respiration was given up. The autopsy showed hemorrhage into the ventricles of the brain. Was, then, the woman "living" during the five hours of artificial respiration, or not. The question, while it may have somewhat the aspects of a metaphysical juggle, is by no means entirely of that nature. For on it might depend the question of survivorship; the question in law of "which died first," involving an entirely different inheritance of property. Again shall the criterion be the cessation of the action of the heart? Brouardel cites a case witnessed by Drs. Regnard and Paul Loye, in which the heart beat for one hour in a decapitated murderer, and he himself has seen the heart-beat persist fifteen, twenty, and twenty-five minutes in decapitated dogs, and in those dying from hemorrhage. It is no easier if we turn to the brain, for its functional activities are no more necessarily co-extensive with life than are those of the heart and lungs. Unconsciousness is normally periodic in sleep, and pathologically it frequently occurs without invoving the cessation of "life." The solution of

the riddle really lies in the fact that "death" is a negative term denoting merely the cessation of "life." This throws us back upon the question of what "life" is. Without any desire to dogmatize on this much-debated question (and leaving others free to inject into it any additional factors or elements that they please), "life" appears to be merely a convenient name for a series of physicochemical processes which avowedly differ much in complexity from "inorganic" phenomena, but which have never yet been shown to differ from them in kind. On the contrary the more we learn about physical and chemical phenomena, the more "physiological" phenomena we are able to explain. The essential of "life" then consists in the *capability* of responding serially and appropriately, by continual adjustments, to changes in the environment. It is not the actual demonstration at every moment of its presence that constitutes "life." For, unless we are to introduce some metaphysical dodge-the-issue (as, for example, "capable of life yet not living, or other empty phrase"), bodies are either "alive" or "dead." What meaning, however, has the word "alive" when applied to the seeds of wheat which grew after having lain thousands of years in a mummy's coffin? Evidently this: A seed represents a collection of chemical compounds which, *under suitable conditions* (of temperature and moisture) are capable of producing, by their mutual interactions, another series of compounds, which, in their turn, are capable of producing, by their interactions, a third series of compounds; the first, second, and third series of compounds representing in their totality respectively the first, second, and third stages in the development of the plant. But, as Ryder has shown, this repetition in heredity is conditioned upon repetition in environment—that is, the seed will respond in a regular serial order only provided the physical and chemical forces act upon it in the regular serial order to which it has been adapted, through countless generations, to respond. If beyond certain rather narrow limits, the forces acting upon the seed depart from the order and extent for which it has become adapted, then something other than the accustomed "normal" development takes place; and the result is some form of "monstrosity." The eggs of fishes when extruded are flabby and collapsed, and in this condition they appear to be in physicochemical equilibrium. Placed in water, however, during the first twenty minutes they imbibe it, swell, and become round and smooth, and fertilization occurs. But after the swelling and fertilization have occurred, the contents of the egg are in a different physical and chemical condition than when first extruded, and this different physical and chemical condition it is which involves the next change of state, cleavage. Yet that the latter change is no necessary outcome of the swollen, fertilized condition is shown by the possibility of inhibiting it indefinitely by a lowering of the temperature. When two cleavage spheres are formed, the physicochemical momenta are different from those acting prior to the first cleavage, and just such as to bring about the redivision into four; and so on; each stage bringing about, under the "normal" conditions, the succeeding stage.

The possibility of the continuance of "life" then depends upon the ability of the chemical compounds which (collectively and at any given moment) we term "the body," to give rise to another similar collection which shall be able *inter se* to maintain a similar adjustment of internal relations to external relations. Conversely, when the formation of such a derivative collection is no longer possible, "death" ensues. Less abstractly put, "death" is the name we give to the inability of the organs to act together with the harmony which characterizes "life." The rupture of the vital harmony does not, however, preclude a certain amount of activity of individual organs. Thus, perfused with blood, or other suitable fluids, the heart may continue to beat, the liver to secrete, etc., though the individual is "dead." This mode of viewing the question seems to be the only philosophical one. For just as there is no possibility of assigning a moment at which, in development, the physicochemical forces pass over into the "vital," so here there is no possibility of saying when the "vital" forces pass over into the physicochemical. All we can do is to set an arbitrary limit, by way of definition, and say that the "individual" is "dead" when the harmony of interaction in the "vital tripod" ceases.

---

## THE CHANCROID BACILLUS, AND EXTRA-GENITAL CHANCROID.

Dr. Lincoln Davis contributes to the *Journal of Medical Research* for June a paper giving the results of his experiments, which add to the evidence already present in favor of the specificity of the bacillus discovered by Duprey in 1889, and by him considered as the cause of chancroid. At the present time there is, the author tells us, general agreement among bacteriologists upon the following points: That bacilli about 1.5 microns long, and 0.5 micron thick, with rounded deep-staining ends and a fainter-staining central portion, occur with great constancy in the pus of chancroidal ulcerations, and less frequently in that of chancroidal buboes; these bacilli occur both singly and in masses, usually outside, but sometimes inside the pus cells, and also in very characteristic chains; in the chancroidal tissues the organism usually stains solidly and the chain arrangement is particularly constant; and it takes basic anilin stains well, but is quickly decolorized by alcohol and by Gram's method. Finally such bacilli have been observed in no other form of ulceration. In 1898, for the first time, the disease was reproduced by Lenglet by the inoculation from a pure culture upon man. Sections from the artificially produced lesion showed the arrangement of the bacillus to be that characteristic for Ducrey's bacillus, and the latter was recovered from the ulcer. In 1901 also pure cultures were obtained by Besançon, Griffon and Le Sourd, and their results have since been confirmed. In 1900 Nicolle succeeded in producing by inoculation the disease in certain monkeys (notably Semnopithecus). The author's series of cases comprised forty cases of genital ulceration clinically resembling chancroid, and in thirty-two cases he found a bacillus corresponding exactly in morphology and staining reactions to

Ducrey's bacillus. In ten of the cases also the characteristic chain arrangement was observed. In eight cases it was impossible to identify Ducrey's bacillus among the varied assortment present, but these negative cases became rarer with the improvement in technique. Ducrey's bacillus was the prevailing organism in the simple ulcers as well as the phagedenic ones, and it was present in equal numbers proportionately, seemingly showing that the virulence of the process depends largely upon the resistance of the individual. Only one case of those which yielded Ducrey's bacillus showed a mixed infection; in this case syphilis later developed. Two of the cases yielding cultures were from extra-genital lesions. This leads the author to allude to Ullman's collection from the literature of sixty-four authentic cases, twenty-two of which occurred on the fingers; in all these twenty-two cases genital lesions also existed. Nine cases were verified by the finding of the bacillus, and four by positive inoculations. One case showed multiple abscesses on the dorsum of the hand. Peterson collected 9,000 cases of soft chancre, 8,992 of which were genital or perigenital (buttocks, groin, etc.), and eight extra-genital, five of the latter being on the hands. Queyrat, of 1,500 cases seen, mentions only five on the hands, genital lesions coexisting in all five cases. In four of the five the Ducrey bacillus was found. The author then reports his own cases, eight in number; six of them being genital, two extra-genital (on the hands), both without co-existent genital lesion. The supposed etiology in one of these last cases was the running of a splinter under the nail, although the possibility of venereal contact shortly after the injury to the finger was admitted by the patient. In the other extra-genital case, a month previously the patient, a tailor, had pricked his finger with a needle; shortly afterward the finger became sore and about a week later tender swellings appeared on the back of the hand and at the elbow, all three localities having been incised previous to his examination at the Massachusetts General Hospital. All the eight cases yielded cultures of the Ducrey bacillus. The author concludes that the organism is present in the pus of the ulcers in the vast majority of cases of chancroid, and occasionally also in that of the buboes; and it may be identified by its morphology and staining reactions, together with its inability to grow on ordinary culture media. Characteristic growth of the organism in a pure state may be obtained on suitable media from genital chancroids direct; also in some cases from the buboes. The growth is most luxuriant in a medium of fresh blood and bouillon, but unmixed human blood is the best medium for obtaining cultures from sources open to contamination. Inoculation of a pure culture in certain monkeys reproduces the lesion, and the original organism can be recovered in culture. The obtaining of the same organism in pure culture from lesions of the hands clinically resembling chancroid, indicates that chancroid may be primary on an extra-genital site. Bacteriological examination of all ulcers of this type is likely to establish a greater prevalence of extra-genital chancroid than has hitherto been reported.

## The Principles of Medical Ethics in the United States.

There has been much misunderstanding concerning the attitude of the Medical Society of the State of New York on the Code of Ethics question, for the original arguments upon which the differences of opinion regarding the desirability of modifying some the provisions of the old rules have become now a part of ancient history. For this reason we take the opportunity of printing the following letter from our distinguished townsman, Dr. D. B. St. John Roosa, contributed to a recent issue of *The Lancet*, giving an account of the fundamental objects that actuated the movement. We do this the more willingly as it presents the views of the Medical Record on the subject, advocated at the time when the discussion was at its height and when party feeling resulted in the formation of radically opposed factions. Happily the recent action of the American Medical Association has reconciled all previous disagreements and has fallen in line with the advanced views regarding the relations of legally qualified practitioners to each other. Thus recent events have proved that the Medical Society of the State of New York was right in its original position, although much in advance of professional opinion at the time.

The following is the letter of Dr. Roosa:

"While making a short stay in London, in reading *The Lancet* of July 4 my attention was arrested by the views of your New York correspondent on the subject of the agitation concerning the code of ethics of our profession in the United States which has been more or less existent since 1882. Quite an opposite view from that taken by your correspondent is entertained by a large number of the profession, especially in the State of New York, on some points of his discussion. I therefore beg, as one of the active participants in this agitation, that I may be allowed briefly to present that view. The Medical Society of the State of New York, a representative and incorporated body of the regular medical profession which has been in existence for nearly 100 years, in the year 1882, having hithero adopted the code of ethics of the American Medical Association, changed this code, chiefly in the matter of freedom in consultation with all legalized practitioners. The State Society was led to this action by the fact that the State, in consequence of the expulsion of homœopathic practitioners from the regular county medical societies of the State some years before, had legalized these practitioners and organized them into a body with powers equal to those of the State Society organized early in the last century. Many in the State Society at that time advocated the abolition of all *written* codes of medical ethics. In the face of great opposition in other States and some in our own, the New York State Society in 1886 went further and abolished all reference to a code in its by-laws. But that society and all the societies represented in it, the New York Academy of Medicine being one of them, has ever since, in spite of the absence of a written code, maintained the highest standard of professional ethics. The object of this important action of the State Society was not to secure consultations with homœopathic practitioners, but to establish a *modus vivendi* with them preliminary to securing their coöperation in the passage of a law making the same requirements of all practitioners of the State as to qualifications for practice within the State. The result was accomplished. Having been placed on an equal footing with the regular profession by that profession itself, as they had been already

by the State, the Homœopathic State Society united with that of the regulars in securing one of the best laws that exists in any country regulating the licensing of practitioners of medicine. This law came into force in 1891. Now, no men or women can practise medicine in our State, no matter what degree or degrees they may have, unless they have passed a satisfactory and rigorous examination on all points in medical science. This examination is conducted by an independent board of medical examiners appointed by the Board of Regents of the University of the State. Homœopaths, regular practitioners, eclectics, even members of the Colleges of Physicians and of Surgeons in London, graduates of Paris or Berlin, physicians from other States of the Union, all must pass this State examination or not be allowed to practise in our borders. The only exception made as to uniformity in the examinations is that homœopathic and eclectic practitioners may be examined with different questions in therapeutics. In other respects the papers are of the same character. This law has been copied in other States of our country, notably by Pennsylvania, Virginia, Illinois, and others. It will be seen by this statement of facts that the Medical Society of the State of New York had a much broader aim than that of "mitigating the restrictions of the old code" in abolishing all written codes of etiquette, and that its action has been followed by the most beneficent results to the profession, results which were fully in the minds of its members when they took upon themselves the responsibility and breasted the obloquy which their action involved. That action has finally been fully vindicated by the sentiments of the various States of the Union as represented in the American Medical Association. This association has hitherto refused representation to the Medical Society of the State of New York, but at the next meeting that representation will undoubtedly be accorded and the strife over the code be ended."

## Registration of Nurses.

Registration of nurses is being strongly advocated in Great Britain, but with true British conservatism the matter is not to be pushed with any undue haste. The question will be considered in all its bearings, before any definite decision is arrived at. However, there is no doubt that the sentiment of the medical profession, of the nurses themselves, and of that portion of the general public which interests itself in the subject, is in favor of the registration of nurses. The supplement to the *Hospital*, June 27, has an article treating of the training and registration of nurses, the greater part of which is devoted to a somewhat sharp criticism of the futility of legislation in connection with registering nurses, that has up to the present obtained in the United States. The article reads as follows: "It is the fashion of those who write and speak most about the registration of nurses to point with scorn to the present state of affairs in England, and to laud the introduction of legislation for the registration of nurses in the United States. Now our American cousins lay down in their registration bills "That nothing shall in any manner whatever curtail or abridge the right and privilege of any person to pursue the vocation of a nurse, whether trained or untrained." (Carolina.) This clause clearly reveals the spirit in which such legislation is enacted in the United States. An agitation is gotten up to secure an act on a particular matter, which is duly passed but never enforced, for the simple reason that no machinery for its enforcement is set up or probably desired. There is no utility in an act of legislature unless that act is so drawn as to define clearly the purposes aimed at, and to secure the provision of funds, and an adequate and properly constituted authority to ensure its enforcement. When passed, none of the American Registration bills fulfil these essential conditions, and for all practical purposes they might just as well have no existence." These strictures are to some extent justified by the facts of the case. In but few States has an attempt even been made to guarantee the efficiency of nurses, by compelling them to offer evidence that they have had a sufficient period of training, and to undergo a test examination. In those States in which efforts have been made to adopt such a course and to introduce bills providing for the registration of nurses, unexpected opposition has been developed against their passage. The Illinois bill was vetoed by the Governor. The good effects of the Carolina bill were nullified by the clause referred to in the *Hospital* supplement, and in no State but New York has a bill been passed likely in any way to improve the status of the nurse. The New York bill, although by no means an ideal one, is an advance movement, for it provides a system of registry for regularly trained nurses who shall have passed a satisfactory examination before a board of examiners appointed by the regents of the University of New York. Nurses passed by the board will each receive a license as registered nurse and may attach R. N. to their names, as may also nurses already qualified by long service. The writer in the *Hospital* supplement also falls foul of the length of time considered sufficient for the training of a nurse in the American acts, *i.e.* two years. He does not think two years enough, but wants an ideal of at least three years training and with a minimum age of twenty-five years for the holder of a license. It is an obvious truth that nurses should be thoroughly qualified for the work that falls to their lot. The only way to reach such an end, is that they should give evidence that they have been well trained, and should pass an examination before they are permitted to act as nurses. It would be manifestly to the benefit of all concerned if every State were to pass bills for the registration of nurses embodying these principles. The status of nurse at the present time is ill-defined, and the whole question of nursing is in an unsatisfactory condition.

## Modern Life and Drug Taking.

The drug habit is said to be on the increase in all civilized countries. Without a doubt such is the case in the United States, and it has been recently reported that in Great Britain drug taking among the population at large is assuming alarming proportions. The *London Spectator*, July 4, has an article on the subject, which treats of the situation from the more obvious standpoints. The writer calls attention to the strain placed upon the individual by the obligations and distractions of modern life, producing nervous affections in profusion, and attributes to these the prevalence of drug taking and of indulgence in stimulants, and gives a tabular statement of the death rates from various causes in Great Britain, during periods of five years from 1861 to 1890, as adding to the force of his argument. He points out that there are two classes of mankind who become slaves to alcohol or opium, those at the apex and those at the base of the intellectual triangle. The first class have recourse to alcohol—which is a sedative and

not a stimulant—because the central activity of its members is exceptional, and whose thoughts are often poured out with such startling originality and profusion, that they endeavor to check them by drinking to excess. They feel impelled to put a break on the mental wheel. On the other hand, those at the base of the intellectual triangle are "a group of human beings whose lives are spent in environments well-nigh stifling to the development of happiness, with the result that they drift into a state of insensible ill-health and inevitable depression, which drives them to seek comparative oblivion in the effect of alcohol or other sedatives."

Thus at the apex of the triangle we find mental and at the base physical misery, and in these facts the remedy for intemperance must be sought. In order to cure disease it is necessary to take away the cause.

The drugs used are many and various, and not difficult to procure. A large number of them are sold over the counter of a druggist's store, as ordinary articles of commerce, among which are the bromides, and other drugs which have a similar action. Such sedative agents have an insidious effect, for while on the one hand "they diminish pain and decrease irritability, on the other hand they lessen the vigor of the organism, alter the quality of the blood for the worse, and tend to shorten life.

As in the United States, so in Great Britain, the more potent drugs, or compounds of them, can be procured with more or less ease. For although, says the writer, "their sale is restricted to registered chemists, there is frequently very little difficulty in obtaining those which are generally known as patent medicines and sold under the protection of the Government stamp. This is especially the case with preparations of morphia."

Regarding the fashion in drugs, it would seem to be—according to the article in the *Spectator*—much the same in England as here. At one time it is opium, then chloral, chloroform, sulfonal, cocaine, and so forth. This fact, however, stands out with sinister prominence, that whatever, the drug of the day may be, many of its victims are overcome by their craving for it; they sink into the drug habit, and either find a premature grave or live on, degraded human wrecks.

The means of obtaining powerful drugs is at the present time too easy. There is no doubt but that the opinion among members of the medical profession throughout the world is identical upon this point. Laws with respect to the sale of such drugs should be made far stricter than they now are, and, further, should be stringently enforced. Drunkenness is probably decreasing, but the drug habit, which is more harmful in every way, is making rapid strides.

---

### A Statistical Study of Intestinal Parasites at the United States Government Hospital for the Insane.

Messrs. Philip E. Garrison, Brayton H. Ransom, and Earle E. Stevenson of the Hygienic Laboratory, U. S. Marine Hospital Service, have been recently making investigations with regard to intestinal parasites found among five hundred white male patients at the U. S. Government Hospital for the Insane. Of the soldiers examined those admitted before 1898 numbered 30 men, 4 of whom, or 10 per cent., had intestinal parasites. Three infections were with trichuris trichuira, and one with hookworms. Soldiers admitted after 1898—This class contained 40 men, 9 of whom, or 22.5 per cent., were infected with parasites, eight infections were with trichuris trichuira, and one with hookworms. Of soldiers returned from the Philippines, 59 were examined, 25 of these, or 42.46 per cent., had intestinal parasites, 15 men were infected with trichuris alone, and one with hookworms alone, 7 with hookworms and trichuris, one with hookworms and strongyloides, and one with hookworms, trichuris, and ascaris. Thus, in the 59 soldiers there were 10 infections with hookworms, 23 infections with trichuris, and one infection with strongyloides, and one infection with ascaris, or a total of 35 infections.

The report says that "the soldiers admitted after service in the Philippines—among whom was found a percentage of infection more than twice as high as in any other class—were for the most part young men, their average age being 30.5 years. The much higher rate of infection in the men from the Philippines can be accounted for by the greater prevalence of the parasites there, and by the poor sanitary conditions under which it was necessary for the men to live during active service in the islands.

The results obtained in these examinations at the Government Hospital would indicate that a large number of the United States soldiers returning from service in the Philippine Islands return with a parasitic infection of the intestines. While the percentage of infection with hookworms among these soldiers was not so high as that with whipworms, its clinical importance is much greater, because of the severe anæmic and nervous symptoms which the hookworm is capable of producing and the danger of this parasite being spread in this country, especially the danger of its being carried to parts of the country where it does not now exist.

The investigators summarize as follows: (1) The results of the investigations show that 13.2 per cent. of the patients examined were infected with intestinal parasites. The parasites found were hookworms (uncinaria Americana, or agchylostoma duodenale), whipworms (trichuris. trichuira), seaworms (oxyuris vermicularis), Cochin-China worms (strongyloides stercoralis) and eel-worms (ascaris lumbricorides). No evidence of infection with tapeworms, flukes, or coccidia was found. (2) Our results differ from those of most foreign investigators principally in the lower rate of infection, in the absence of tapeworms, and in the presence of hookworms, and of Cochin-China worms. (3) The results show that the percentage of infections tends to vary inversely with the age and with the duration of institutional life of the patients. (4) They also indicate that army life is conducive to parasitic infection of the intestine, and, moreover, that a high percentage of the United States soldiers returning from service in the Philippine Islands have intestinal parasites. (5) The presence of a moderate number of worms in the intestine seems to have no relation to the presence of undigested starch and meat in the dejecta, or to the litmus reaction of the fæces.

The researches at the Hygienic Laboratory of the Marine Hospital Service have definitely proved, what was fairly well known before, that the Philippine Islands simply swarm with parasites, and that despite the greatest care soldiers serving there will become the victims to parasitic infection of the intestines. As to any connection between parasitic infection and insanity the investigators make no reference.

---

### The Modus Operandi of Saline Purgatives.

It has generally been supposed that these purgatives effect catharsis by diminishing or preventing absorption of water from the intestine—that is, by decreasing osmosis into the blood vessels through con-

centration of the solution outside of those vessels to approximately the density of the blood. Still, many years ago it was noted that hypodermic injections of magnesium sulphate in small dose (3 grains) would produce catharsis. Dr. J. B. MacCallum, working over this subject, at the University of California, finds that, in rabbits, barium chloride, and sodium citrate, fluoride, sulphate, tartrate, oxalate, and phosphate act as purgatives not only when introduced *per oram*, but when administered hypodermically. The purgative action is produced first by an increased peristalsis, and secondly by increased secretion; both of which conditions can be directly observed. Intravenous injections caused increased peristalsis within one minute, but when introduced into the intestines five times the amount is required and the effect is not manifested for ten to fifteen minutes. This seems to indicate that absorption must precede purgation, and that the effect is produced by way of the nervous system. At any rate the action is not due to the prevention of absorption of water by the gut. Moreover, Loeb has pointed out that the salts which produce purgation are precisely those which he has found to produce contact irritability, muscular twitchings, and hypersensitiveness of the nervous system, and has suggested that the increased peristalsis is due to increased irritability of the intestinal nerves and muscles. The correctness of this view seems to be shown by MacCallum's observation that the simultaneous injection of calcium salts (which, as Loeb has shown, decrease nervous irritability), in the amount of seven centigrams. MacCallum remarks that there is, then, a perfect analogy between the purgative effects and its inhibition by calcium, and the production of and suppression of muscular twitchings and nervous hypersensitiveness, and, finally, that the administration of calcium salts for diarrhœas (especially those which accompany hysteria or nervous excitability of any sort) here finds its rationale.

### The Mosquito Plant.

That mosquitos are chiefly, if not wholly, instrumental in spreading malarial fever has been definitely decided. The object then at the present time is to devise efficient means of destroying mosquitos, or at any rate of preventing them from reaching human beings so as to be able to bite them. A successful wholesale destruction of the disease, bearing insects can hardly be looked for, although in the vicinity of towns much can be effected in this direction. Measures designed to keep mosquitos out of dwellings and to protect the exposed portions of the person when abroad, will be the principal means of defence for some time to come. There has recently been an interesting correspondence in the *London Times*, regarding a plant which is said to have the property of quickly ridding a district of mosquitos. Sir George Birdwood, a recognized authority on botany, says that this plant and allied basils have been known from time immemorial throughout India, as a defence against mosquitos and a prophylactic in malarial districts. He instances some striking examples that came under his own notice of the manner in which this plant acted as extirpator of mosquitos. Capt. H. D. Larymore, writing from Northern Nigeria, Africa, gives similar testimony with regard to the plant. He says, "I can personally testify to the extraordinary effect produced on mosquitos by the pleasant odor of the fresh leaves of the 'mosquito plant' (Ocimum viride), and by placing two or three pots containing growing plants in each room and along the windward veranda, a house can be kept practically free from the insects. One of the malaria-giving specimens which I caught alive and tenderly inclosed within a leaf of the plant lost consciousness in a few seconds." If this plant really has such a magical effect upon mosquitos as is ascribed to it, it is assuredly deserving of the attention of those directly interested in the extirpation of the insects. It certainly would not be amiss if the "mosquito plant" were given a trial in certain districts of the United States.

## News of the Week.

**Increase in Smallpox and Typhoid Fever in Philadelphia.**—There were reported to the Philadelphia Board of Health for the week ended August 1 109 cases of typhoid fever, with 14 deaths, and 29 cases of smallpox, with 3 deaths. There were reported also 54 cases of diphtheria, with 3 deaths, and the same number of cases of scarlet fever, with 4 deaths. The number of deaths among infants was smaller, being 92 as compared with 123 for the preceding week. The Bureau of Health has organized a series of lectures to mothers on the summer care of infants, to be delivered in the populous districts by a corps of physicians. The total number of deaths for the week was 485, as compared with 500 for the preceding week.

**Crude Drugs from Domestic Sources.**—A number of common plants, occurring in some cases as weeds, furnish, when properly collected and cured, crude drugs such as are now imported in large part from Europe and elsewhere. The Bureau of Plant Industry of the U. S. Department of Agriculture is now engaged in the preparation of a Farmers' Bulletin pointing out the desirability of satisfying the demand for these drugs from domestic sources. The bulletin will contain descriptions and cuts of the plants, and methods of collecting, handling, and curing will be given. In order to increase the effectiveness of the bulletin it is thought necessary to bring the prospective collector in touch with buyers. Therefore circular letters are being sent to dealers in drugs asking if they wish to be included in the list of firms to whom the bureau is authorized to direct those wishing to submit samples and get prices.

**Many Applicants for Medical Practice License in Massachusetts.**—The examination of applicants for registration in medicine recently held in Massachusetts is said to have demanded the largest committee room in the State House, owing to the fact that upward of two hundred applicants applied for the examination. Five examinations for several years past have been given annually, but it is likely that this number will be increased with the increasing number of applicants.—*Boston Medical and Surgical Journal.*

**A Record of Cancer Investigations.**—In view of the constantly increasing number of treatises and journal articles relating to the subject of malignant neoplasms, the "Committee on Cancer Research," which was established in Berlin in February, 1900, has decided to establish a periodical as a central organ for all those interested in the subject. The journal, the title of which will be *Zeitschrift für Krebsforschung*, will be published from time to time as material accumulates. The editors will be Drs. D. v. Hansemann and George Meyer, the publisher Gustav Fischer of Jena. The journal will be published in pamphlet form, and 640 pages will constitute a volume, the price of which will be 20 marks.

**Bacteriologist for the Philippines.**—Dr. Charles B. Hare of Ann Arbor has accepted the appointment of government bacteriologist in the Philippines, at a salary of $1,500. He contracted the bubonic plague at one time, while working in the laboratory of the University of Michigan.

**Philadelphia Spitters.**—War has been begun against the defilers of sidewalks in Philadelphia, and many men have been arrested recently and fined for spitting on them in defiance of the law. It was announced in the papers some time ago that a similar campaign had been begun against these nuisances in New York, but no results are yet evident.

**Too Many American Congresses on Tuberculosis.**—We received some time ago a circular signed by Dr. Daniel Lewis of New York, as president, announcing that the American Congress on Tuberculosis would not be held in St. Louis in 1904, for the reason that the International Congress on Tuberculosis would be held in Paris the same year. We have also received a circular signed by Dr. E. J. Barrick of Toronto, as president, announcing that the American Congress on Tuberculosis would be held in St. Louis in 1904. We assume that the two congresses are antagonistic, since we are warned in one of the circulars that no communication is genuine without the signature of the secretary of that individual congress, yet we find that Dr. Barrick of Toronto is the president of one congress and the third vice-president of the other, and that Dr. J. G. Adami of Montreal is an honorary president of one and a member of the committee on pathology and bacteriology in the other. That is almost as confusing as the overlapping of membership in the two New York County medical organizations.

**Dr. Henry W. Berg.**—Through one of the inexplicable accidents which happen in even the best regulated printing establishments, the name of the author of the article on "Chronic Postdiphtheritic Laryngeal Stenosis as a Cause of Persistent Intubation of the Larynx," published in the MEDICAL RECORD of August 1, was printed Henry W. E. Berg. The initial "E" inserted itself without reason and to the regret of author and editors.

**The Chicago Board of Health.**—The Civil Service Commission of Chicago recently made an investigation of the Health Department of that city, and, as a result of its findings, brought specific charges of laxity in the methods of the department. Among other things, the report of the commission found that: "Complaints made to the department are not, at the time they are received, entered in any permanent record, but they are distributed in the boxes of the various inspectors, who then sort them over and reject such as they see fit to reject, making investigations of the remainder. These latter are entered in a permanent record book. When a complaint is turned over to an inspector there is no system by which the work of the inspector is supervised. It is wholly within the discretion of the inspector whether the nuisance complained of is abated within six days or six months, or whether it is abated at all. The 'stay book' shows that after prosecutions have been begun action is stayed at the discretion of almost any one connected with the department, not of one responsible officer, and there is no supervision of a case after it is stayed, so that in most cases when a stay is ordered it is an equivalent to a nullification of the complaint. Not only have a number of people in the department the authority to grant stays, but these officials act in most instances at the suggestion of persons wholly outside of and in no way connected with the department." The Commission holds the Health Commissioner, Dr. Reynolds, directly responsible for what it calls this "mischievous policy of delay and concession," and it adds that the health inspectors have become careless in their work and discouraged, since there is no incentive to good work, action being so seldom taken on their reports. Dr. Reynolds has denied most of the accusations against the department, and explained others by saying that the necessary improvements would in many cases be so costly that the carrying out of the inspectors' suggestions would amount practically to confiscation of the property. The Mayor has sustained the Health Commissioner in so far as to retain him in office, but has warned him that the work of his department must be bettered.

**The Health of Pittsburg.**—It is feared that typhoid fever will become epidemic in Pittsburg unless the condition of the water supply soon shows an improvement over what prevails at present. The number of new cases of the disease amounts to from sixteen to twenty a day.

**The Vanderbilt Memorial Hospital in Newport.**—The hospital erected at Newport, R. I., by Mrs. Cornelius Vanderbilt, in memory of her late husband, was turned over to the trustees of the institution on August 1, the transfer being made by Mrs. Vanderbilt by letter. In the letter Mrs. Vanderbilt also announced that she would endow the building. The building is of Indiana limestone, three stories high. The ground floor is devoted entirely to the out-patient department. On the second floor are the committee rooms and several wards. The third floor contains several wards for children.

**Plague in San Francisco.**—It was believed that a plague had been eradicated from Chinatown in San Francisco, only two cases having been discovered there during the first six months of this year. In July, however, a slight recrudescence occurred, four cases being reported during the month. The health authorities of the city are employing the same rigorous measures to stamp out the disease that were inaugurated in compliance with the determination of the convention of health experts in Washington last November. A regular inspection is made of the quarters occupied by the Chinese, many of the rooms are disinfected, the sewers are being flushed, and a bounty is paid for dead rats.

**Obituary Notes.**—Dr. ALBERT JEREMIAH SCHUREMAN of Newark, N. J., died on July 28 in the home of his brother, Dr. Charles A. Schureman, in that city. He was seventy-five years of age. His death was due to a general physical breakdown. He was a graduate of the Medical Department of the New York University in the class of 1872. He was well known not only as a physician but as a writer and an artist.

Dr. FRANCIS F. MILES, a well-known practitioner, died in Baltimore on July 30, at the age of seventy-six years. He was born near Charleston, S. C., and was graduated from the Medical College of the State of South Carolina in 1849. He served through the Civil War in the Confederate Army. He had practised in Baltimore since 1867.

Dr. GOTTHOLD PAPE died at his home in Hoboken on August 2, at the age of sixty-one years. He was born in Germany and obtained the degree of Ph.D. from the University of Göttingen. He came to this country just before the breaking out of the Civil War and served in the Union Army in the Thirteenth New York Independent Battery of Light Artillery. He was graduated from the Medical Department of the New York University in 1880 and settled in Hoboken, where he practised medicine up to the time of his death.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—OPEN-AIR TREATMENT—DECIDUOMA MALIGNUM—HEALTH CONGRESS—ORTHOPEDIC HOSPITALS—"JOURNAL OF THE ROYAL ARMY MEDICAL CORPS"—TWO INQUESTS.

LONDON, July 17, 1903.

THE special session of the General Medical Council met on Wednesday. The chief object of the meeting was to consider the impulse created by the conduct of the two royal colleges. You will remember that these have repudiated for a long time the control of the council over the teaching institutions they may recognize. The dispute has been discussed at intervals for the last nine or ten years, but last year it seemed more likely to come to a head. The recalcitrant colleges stood on what they held to be their legal rights under their charters. Most people think if it comes to a fight between royal charters and acts of Parliament the latter must prevail. That would be good for medical education which, with all its faults, the council has done much to improve. The report of the committee which exposed the valuelessness of the first year's education at schools for boys accepted by the colleges was, after discussion, adopted.

Dr. Moore told the council that the College of Physicians considered the council had no power whatever in regard to the regulations, but viewed the General Medical Council as a criticising body—as such they considered its criticisms with the utmost deference and respect.

That being the position of one college, the other disputes its action and looks upon the interference of the council as *ultra vires*. You see, the matter has made no progress. Sir Victor Horsley who is not afraid to follow his opinions by action, proposes to represent to the Privy Council that these preliminary examinations are inadequate. The matter is being discussed as I write.

The open-air treatment is making renewed progress with the public. On Wednesday Lord Roseberry opened the new pavilions of the Victoria Consumption Hospital, near Edinburgh, which has been at work for some seven years. The extensions are to cost about £7,000, the original property having been purchased for £17,000. Dr. Philip said the expenditure on the institution would be £3,000 in excess of income. All the beds but eight are free. The eight are for those who can afford to pay £1 1s. per week, which sum does not cover the cost. In fact, the cost per bed is from £100 to £120 per annum. Dr. Clouston, President of the Edinburgh Royal College of Physicians, in his speech, dwelt on the educative value of the hospital.

Lord Roseberry said it must have been a shock to many to be told that consumptive patients were to be exposed for their cure to all the worst that the climate of Scotland can do, and yet it is an undoubted fact that that exposure has been of the greatest benefit to many cases. Some slept in the open air all last winter, and sometimes snow had to be taken from under their beds in the morning. With the facts before us, said his lordship, "we may lift up our hearts with thankfulness to the Almighty, who has let us into the secret of this great healing prescription, and to those men who have given their lives and their time to the relief of this form of disease." He concluded with an eloquent appeal for more money, and donations were announced amounting to £1,489.

Deciduoma malignum has occupied the thoughts of gynecologists for several weeks. Dr. Teacher brought the subject before the Obstetrical Society, which gave two evenings to it last month. In 1896 a committee of that society reported that there was nothing in the specimens submitted to justify the name or the supposition that they were of decidual origin. In 1902 Dr. C. Lockyer read a paper which impugned this conclusion, and induced some to accept the view of Marchand that these tumors originate in the corionic epithelium.

Dr. Teacher's elaborate paper presented much more evidence to this effect, and those best able to judge seem to have become convinced. As an eminent professor writes to me "it is now almost unanimously agreed that there is a special form of malignant growth, taking its origin from the fetal elements of the decidua, and giving rise to metastatic deposits."

The question of the nomenclature of these growths was raised at the society and several names proposed, but deciduoma malignum has been so long and so generally applied that it was felt to be hopeless to displace it as a clinical term, although pathologically incorrect.

A resolution that a minister of public health should be appointed and the medical department of the Local Government Board enlarged and made into a health ministry occasioned a rather lively debate in the Sanitary Congress last week. On the one side it was said the minister should not be a politician but should attend the cabinet when health questions were discussed. On the other it was said a minister would only hamper the medical officers of health, who most of all needed freedom—freedom from the influence of property owners on local councils. A cabinet minister would be chosen as a party man—not for special knowledge. From this point the discussion degenerated into a talk about the qualifications of politicians and cabinet ministers—a talk which could have no influence on the powers that be.

A paper was read on the work of the West Riding Rivers Board which held out the prospect of purification as most hopeful. When the sewage of the boroughs has been removed the rivers will again be fit for fish.

Another paper by a medical man contended that overfeeding rather than over-crowding is the chief cause of fevers. He is reported to have declared that twice a day is often enough to feed an infant, and adults from twenty-one to fifty years of age should be content with one meal a day. After seventy-five they should know themselves what was good. I wonder if he has brought up babies of his own.

Prof. Clifford Allbutt's address was one of the most interesting events in the congress. He entered a tilt against the theory of the survival of the fittest. If the most vigorous in body were really the salt of society the elimination of the unfit by disease would be too rough a method of compassing the survival of the fittest. When philanthropists raised the cry of degeneration, physicians were not to submit to be told that medicine must bear part of the blame. To proclaim that preventive medicine could improve all bad stocks up to the average and the good ones infinitely above, was more than he dared to suggest; but he called upon the congress to declare that public health would do it better than public disease, and to urge the Darwinian to study his own origin more closely than he had yet done, and so learn that even unfitness is not uncaused, so that it would be more to the purpose to search for its various causes than to look to blind readjustments after degenerative influences had done their work.

Major Ronald Ross, C.B., gave a lecture in which he related the success of a French company which had followed his advice as to the extermination of mosquitos, with the result that malaria began to decrease within six months. The suppression of the insects has been nearly complete.

The Institute of Preventive Medicine is henceforth to be named after Lord Lister. The name of Jenner, as I reported to you, had to be given up on account of its prior use by another body.

The scheme to amalgamate the Royal and the National Orthopædic Hospitals has been approved by the governing bodies.

The *Journal of the Royal Army Medical Corps* has made its appearance under the editorship of Major R.H. Firth. The first number contains many things of interest to the profession generally, and, of course, is full of that especially interesting to the corps.

Two inquests on medical men in one week are rare. Drs. S. A. Bernays, aged fifty years, died at St. Thomas's hospital while under an anæsthetic. At the post-mortem he was found to have been suffering from chronic tuberculosis and death was supposed to be due to cardiac failure.

The other inquest was on Dr. A. E. Wainwright, a young man of twenty-five years who was acting as a *locum tenens*. He was seized with abdominal pains and rapidly succumbed. The inquest was adjourned for an analysis, but that shed no light on the case, and at the adjournment an open verdict was returned.

## THE PROFESSIONAL NURSE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: The so-called "Professional Nurses" have been making strong endeavors, in different States, with some success, for direct professional registration in the laws of the land and State registration on the same or similar lines to those accorded to the medical profession. That this is a justifiable move is beyond question. It should guarantee to the public a means of distinguishing between the trustworthy and competent person and the contrary by signifying the graduated from the non-graduated nurse. The guarantee, however, is, by no means, infallible. Some "training schools for nurses" are still too much "trade schools," even as there are still too many such among our medical schools. The question at issue is, how much fundamental knowledge should a professional trained nurse have. By fundamental is meant scientific knowledge, fundamental acquaintance with the "theories" of the work and the "reason why" of his or her

acts. That a man or woman can be trained or drilled to be reliable in work, and yet know little or nothing of the science of it, even as a soldier can be drilled in his duties and still know nothing of the science of war is not only self-evident, but practically even more than the present training schools have generally attained to. A writer on this subject has recently claimed that the trained nurse should be competent to make every clinical test of urine, blood, or diseased product. That can be done even as an engineer can be taught to run a locomotive and yet know nothing of the science of mechanics. Another question is, who should decide on the standard of education of the professional nurses—the nurse organizations, the faculties or managers of the training schools, or the medical profession? It would seem that that question should be entirely in the hands of the medical profession. If the physicians and surgeons do not know what is required of the nurse, who does? As to the "faculties" of training schools, their opinions are not worth much where those schools are sort of independent institutions, having hospital connections, but not a part of great public hospitals. The training schools are more or less like the medical. Too many of them are of a semi-private nature, for the "good" of those directly interested, the public and the student-nurses being consistently and persistently exploited for that "good" and little else.

The Organization of Professional Nurses, like many a medical society, have also the same weakness. They are liable to get under the control of ambitious persons who desire to shine before the public. What is worse, these "leaders" are saturated with a "will-o'-the-wisp" idealism which is pure moonshine, shadowed by intellectual cloudiness.

To return to that fundamental question—does the professional nurse require a more or less profound education in the scientific bases of medicine in connection with an exact training in practical routine? If so, how much, and where is the nurse to get that scientific instruction? Certainly not in any of the existing training schools as now organized. The "probation course" of two, three, or six months, or even a year, generally demanded is of little or no use except to obtain a very general idea of the student's fitness, physical more than mental. It is largely comparable to the "one year's reading with some practitioner," now traditional, that formerly prevailed in our medical education. If the medical profession and public service require scientifically educated nurses, then that education must and should be given in institutions entirely free from any hospital connections, and should be free. In other words, the respective States should establish a State normal or preparatory school for nurses where these fundamentals and all laboratory drilling should be taught. The term should be of two years' duration, with three months' vacation between the first and second year. Graduated students should then be apportioned out to the respective public hospitals and institutions for another term of two years. Finally, on receiving a certificate of competency from the hospital, the student-nurses should be examined by a State board, registered, and given their diploma of competency. While private, or semi-public (endowed) hospitals might have the privilege of employing uncertified attendants they should be strictly forbidden issuing any certificates indicating any kind of proficiency to any such employees, and if requiring "professional" nurses should be obliged to apply to the State Board of Registration for them. Complaints as to unfitness or improper conduct of registered nurses should be made to the State Board of Registration, which should have the power to place the nurse on "probation," or to withdraw a certificate altogether in warranted cases. MEDICUS.

---

**A Pathognomonic Sign of True Chronic Maxillary Sinusitis.**—G. Mahu calls attention to the fact that in true chronic maxillary sinusitis, the mucosa rapidly increases in thickness even during the early stages, so that it becomes spongy and myxomatous in appearance. As a result, the capacity of the sinus is considerably reduced. This is determined in the following way: The patient sits erect, and after the pus is washed out of the antrum a syringeful of water is introduced into the cavity, care being taken to drive the piston home. Next the water is sucked out of the cavity and the quantity is measured. It represents the capacity of the antrum up to the level of the ostium. Mahu concludes that when the quantity of fluid withdrawn in this manner is less than one and a half cubic centimeters, the case is one of true chronic sinusitis.—*Journal of Laryngology.*

# Progress of Medical Science.

*The Boston Medical and Surgical Journal, July* 30, 1903.

**Efforts to Abate the Mosquito Nuisance in Brookline.**—H. Lincoln Chase describes his efforts in this direction. All pools, ponds, ditches, and other breeding places, including catch-basins, were located upon the town map. The approximate areas were determined, and the number of catch-basins ascertained. Breeding places of culex and anopheles were determined in order to learn the proper intervals for treatment, whether every three or four weeks. The public dumps and other places where accidental receptacles of water were to be found were located. Light fuel oil was used. In ponds and pools one ounce of light fuel oil was used to fifteen square feet. If there was luxuriant vegetation in them, an excess of one-quarter of the original amount was added. If there was a clear water surface, one-sixth more than usual was added. After spreading the oil, a puddler violently agitated the water with a hoe. The shallow pools, if not large, were filled in. Many small pools were drained or filled. The results of this work were most favorable.

**The Need of a Supplementary Lantern Test for the Proper Examination of Color Perception.**—Charles H. Williams declares that a very extended use of the Holmgren test in the hands of many examiners is now showing that some cases are able to pass this test correctly and without hesitation, who, when examined with the lights from a distant signal, may be unable to distinguish the red or green with any reasonable degree of certainty, and, in fact, often confuse these colors. This occurs most frequently in cases of acquired defect in color-vision caused by excessive use of tobacco or alcohol or by a combination of the two. In such cases there is often a small defect in the central part of the retina, so small that the retinal image of the skein of worsted is large enough to be formed partly within the affected area and partly beyond it, and if at any part it falls on healthy retina its color can be at once recognized. If the object is small, like a distant signal light, the retinal image is formed wholly within the affected area, and the color is not recognized. In addition to the test with different colored lights, it is important to make the test with a light whose intensity can be varied by fixed amounts; for in some cases the defect depends upon the intensity of the light. The writer, for this purpose, has made an electric lamp with a specially constructed rheostat in the base, through which the current for the two incandescent lamps can be passed. The resistance can be varied from nothing to 150 ohms. This lantern test is now used on certain roads in addition to the Holmgren worsted test. With these two tests carefully made it is reasonably certain that no dangerous case of defective color-sense will be passed. When the defect is acquired, improvement may come from removing the cause. But in the congenital cases no treatment will be of much use.

*Journal of the American Medical Association, Aug.* 1, 1903.

**Acute Epiphysitis Causing a Condition Subsequently Simulating Congenital Hip Misplacement.**—John P. Lord reports an illustrative case occurring in a child of two years. The Lorenz-Hoffa cutting operation was undertaken, and this showed the original trouble to have been a healed funnel-shaped depression over the capsular ligament, marking the site of the former sinus through which the destroyed epiphysis had been discharged as pus and débris. The capsule had been converted into a dense ligamentous structure. The opinions of several orthopedic surgeons are cited to show that there is small prospect of success from treatment in many of these cases, and that active surgical intervention is of doubtful utility.

**Tuberculosis of the Mammary Gland.**—A. H. Levings shows that tuberculosis of the mammary gland is not an infrequent condition, but one which goes unrecognized, a statement which is confirmed by the fact that up to 1898 only fifty-seven well-authenticated cases had been reported, and yet he has himself seen seven cases during the past two years. He summarizes his paper as follows: The process may remain for months or years in the form of hard, irregular, and fairly circumscribed nodules. Liquefaction and pus formation are secondary and later processes. The disease attacks the breast most commonly during menstrual life, and occurs with the greatest frequency in single women. The condition is more often primary than has been generally supposed, and both glands are often implicated nearly simultaneously. Palliative treatment may be practised when the process is circumscribed, but when diffuse, radical measures should be recommended.

**The Treatment of Uncinariasis.**—Thomas A. Claytor says that as the primary infecting agents, the eggs, are found in the evacuations, and it is well known that the embryos can not live without air, it is advisable to adopt Sandwith's suggestion regarding prophylaxis, *i. e.* the use of trench latrines outside of infected villages. The infection of human beings takes place chiefly through infected water or food, or through contaminated hands carrying the parasite to the mouth. Thymol is the remedy *par excellence* in this disease. It is best given in two doses of thirty grains each, at 8 and 10 A.M., and this should be followed two hours after the second dose by magnesia or castor oil. Thymol being a poison, its action should be carefully watched. Ordinarily two or three doses are sufficient to effect a cure, but occasionally an obstinate case is encountered. The author closes his paper with an account of an investigation made upon dogs to determine the best method of administering the thymol. An alcohol solution gave rise in dogs to aspiration pneumonia, while the dry powder caused no serious results. He thinks it probably safe to give 2 to 4 gms. of thymol to a human being, followed by one or two tablespoonfuls of brandy, and later by a purge. The alcoholic solution causes a more rapid expulsion of the parasites. The stools should be examined weekly for eggs, and the thymol treatment continued so long as they are present.

*Medical News, August* 1, 1903.

**Pustulation and Its Accompanying Secondary Fever a Complication and Not an Essential Symptom of Smallpox.**—Jennie C. Drennan states that, unfortunately, instead of vesiculation being the final cutaneous lesion in smallpox there is a subsequent one, pustulation, which the writer believes is the result of a secondary infection by pus organisms, which are ever present in the skin. On the cessation of the excretion of the toxins of the smallpox germs by the death of the latter, these pyogenic organisms will find the vesicular fluid a suitable medium in which to flourish. This vesicular serum soon becomes turbid from the rapid development of these pus germs and the vesicle becomes a pustule. Secondary systemic irritation results with a rise of temperature and a second inflammatory reaction around the foci of infection. In the treatment of smallpox, injection of a toxic serum obtained from a cow suffering from the initial symptoms of cowpox should be given in the stage of invasion. Cleanliness and disinfection of the skin, and the internal administration of calcium sulphide to prevent pustulation, are indicated, also opening of all vesicles. The prevention of pustulation will abolish pitting. Symptoms should be treated as they arise.

*New York Medical Journal, August* 1, 1903.

**Dhobie Itch.**—Charles F. Mason distinguishes three varieties, two mycotic and one bacterial. The former are easily recognized by the festooned rings with raised margins and by the microscopical findings. The latter is characterized by an eruption of vesicles, usually about the axillæ or groins, unattended by constitutional disturbance. This form demands thorough cleanliness of the parts and of the underclothes, sponging twice daily with 1 to 1,000 bichloride solution, and dusting with a powder composed of equal parts of zinc oxide, boric acid and starch. In the mycotic varieties the edges of the rings should be painted with tincture of iodine, or an alcoholic solution of corrosive sublimate, or a 10 per cent. salicylic-acid ointment should be applied. The word "dhobie" in India means laundryman, and indicates the popular belief that this is a filth disease.

**An Improvised Method of Operating for Varicocele.**—Lucien Lofton takes up the cudgels in defence of the old operation of ligation, and describes his method of doing this operation. The spermatic cord and artery are carefully separated from the mass of veins, and the latter is then transfixed with a large curved surgeon's needle, armed with catgut. The essential point of the operation is to make the needle describe a half circuit of the interior lining of the scrotum, and come out of the original opening. By this procedure the veins are immediately anchored to the inner side of the scrotal wall, and the patient is thereby enabled to continue his business without a day's interruption. The tying of the ligature should be done gradually, so that if the cord and artery are by chance included in the ligature the severe pain produced will call attention to this fact at a time when it can be remedied. Recovery takes place in about four weeks, and complete atrophy in about six months.

**The Death Rate of Pneumonia.**—Thomas J. Mays gives an interesting study by the graphic method of the vital statistics regarding pneumonia, heart disease, and phthisis. For the most part these figures cover the period from 1876 to 1902, and are taken from the States of New Jersey and Rhode Island, the District of Columbia, and from eleven prominent cities. The tracing from Chicago is peculiar in that it shows an increase in the death rate from pneumonia of 350 per cent., and from heart disease of 450 per cent. A composite chart, built on the combined average death rate for all the places mentioned, shows the total increase of pneumonia to be not quite 10 per cent., and of heart disease, 85.85 per cent. The author concludes that there is no good reason for alarm concerning the ravages of pneumonia, because its highest death rate occurred in 1896, and since then has declined 21.17 per cent. In all of the places considered there has been a reduction in the phthisis rate from the early eighties to 1898, and since then a general net increase. The natural average decrease in the death rate of phthisis is shown to be between 2 and 3 per cent. The figures also show that deaths from heart disease are increasing.

*American Medicine, August* 1, 1903.

**Bradycardia as a Symptom.**—Roland G. Curtin states that bradycardia has been observed as occurring during the course of many acute and chronic diseases. A symptom which is so common, and which occurs in such a multitude of widely different diseases, can be of but small diagnostic value. As an aid in prognosis it would appear that, given a constitution not undermined by disease, and a gradual subsidence of the primary cause of the slow pulse, bradycardia need not necessarily be regarded as a particularly grave symptom. On the other hand, if it is associated with or caused by a depressing chronic condition, especially of the cardiovascular system, it becomes a most serious symptom. When accompanied by anginose symptoms it is frequently followed by sudden death.

**Appendicitis as an Incident in Development.**—Woods Hutchinson believes that a survey of the conditions of the cæcoappendix in different forms of life points irresistibly to the conclusion that in our own ancestry, beginning as a large, voluminous, and actively functional pouch, the concentration of nutritive qualities of the food-supply, the dropping of the purely herbivorous or granivorous diet in the rodents, the acquisition of a diet of chiefly fruit, nuts, insects, small birds and their eggs in the lemur and in the monkey, and finally of a diet almost purely of nuts, fruit, and small birds, in the anthropoid apes, have resulted in its constant and steady diminution in size and importance, and unfortunately for us, in the last two steps of the process in a markedly disproportionate degree of recession in the distal two-thirds of the pouch. The process goes on in the direction of eliminating and completely obliterating a superfluous and no longer useful part of our alimentary tract. Any remnant of tissue, no matter how insignificant, which no longer serves a useful purpose in the struggle for existence, is sooner or later doomed to complete extinction.

*The Lancet, July* 25, 1903.

**Susceptibility of Criminals to Atmospheric Changes.**—W. Norwood East, as a result of an inquiry extending over three years, and comprising observations on 700 prisoners, concludes that, with the possible exception of temperature variations, the criminal is unaffected by atmospheric changes. The fact is emphasized that the normal individual is often materially influenced by such changes, and that the results of this investigation afford additional confirmation of the author's former contention that the criminal is insensible to external impressions.

**Influence of Locality and Surroundings on Recurrence of Malignant Disease after Operation.**—D'Arcy Power reports seven cases occurring in his own experience, and then suggests that certain modes of life, certain kinds of diet, or, in short, conditions leading to a lowering of the general standard of health, are especially favorable to the development of malignant disease. He considers it extremely probable that the recurrences in malignant diseases are not really so capricious and arbitrary as they now appear to be, and solicits the coöperation of those who are favorably situated for such observations in solving this problem.

**Hepatectomy for the Removal of Riedel's Lobe.**—Charles Barrett Lockwood describes the various forms which this rather rare abnormality of the liver may assume, and then reports a case in which he was compelled to resort to excision of this lobe in order to relieve severe and persistent pain. At first the young woman was supposed to be suffering from a displaced and movable kidney; subsequently the symptoms pointed so strongly to appendicitis that the appendix was removed, but was found to be normal. After keeping the patient under observation for a number of months it was considered justifiable to excise the tumor, and this was done on

February 28, 1903, with complete and permanent relief of the pain. The excision was done in such a way as to leave two flaps of liver tissue, which were sutured together with twisted silk. Hemorrhage was easily controlled by an encircling suture buried in the liver substance. It is interesting to note that the gall-bladder was perfectly healthy.

**Enzymes in Tumors.**—Arthur Harden and Allan Macfadyn present a preliminary communication on a conjoint research made by the bacteriological and chemical departments of the Jenner Institute on the intracellular physiology of the epithelial cells in health and disease. They made use of fresh cell juices, obtained by cold grinding methods, from normal as well as from diseased epithelial tissues, and studied the nature of the enzymes present as far as possible by quantitative tests. The control experiments were made upon the normal tracheal epithelium of the ox, and resulted in revealing the presence of an invertase, an amylase, a maltase, and a proteolytic enzyme. So far, lactase and rennin have not been detected. The diseased epithelial tissues were chiefly cancerous tumors of the human breast. The enzymes discovered in these tissues are: an invertase, a maltase, an amylase, proteolytic enzymes, acting in acid and alkaline solutions respectively, a catalase and an oxidase, together with traces of a lipase and possibly of a peroxidase.

*British Medical Journal, July 25, 1903.*

**Treatment of Atrophic Retinæ with Retinal Extract.**—Robert W. Doyne says that, so far as his observations go, improvement by this method of treatment can be expected only in cases of retinal atrophy in contradistinction to nerve atrophy. The cases in which he has had marked improvement have been retinitis pigmentosa, retinal degeneration in high myopia, retinal degeneration in choroiditis, and tobacco amblyopia. Cases of asthenopia from functional exhaustion should be benefited.

**Two Cases of Fracture of the Base of the Skull, in Which Recovery Followed Venesection.**—Stephen Paget reports two cases of this nature. In one case, that of a young man, there was profound unconsciousness thirty-six hours after fracture of the base of the skull, with a temperature rising rapidly to 104°, and the intensest degree of Cheyne-Stokes breathing. He was dying. But as soon as he was bled to 20 oz. plus 12 oz., he began to get better and made a complete recovery. If venesection in such cases could restore consciousness more or less for a few hours only it would still be a valuable method, but these cases show that it may bring about recovery.

**The Causes of Acute Abdominal Pain in the Healthy, Exclusive of Traumatism.**—J. Lynn Thomas states that umbilical or circum-umbilical pain is a common sign of grave abdominal lesions in any locality. He attaches little significance to the absence of hepatic dulness. Of more importance is the degree and continuity of rigidity of the abdominal muscles under prolonged examination with the patient's thoughts diverted. The frequency and condition of the pulse are of considerable value in estimating the gravity of the patient's illness. Temperature is a factor of questionable value in forming an opinion as to the necessity of surgical interference. Vomiting is one of the least significant symptoms, from a purely surgical standpoint. The writer concludes by reviewing cases of gallstone, thrombosis of the superior mesenteric vessels, extrauterine pregnancy, and gastric ulcer.

**Influenzal Orchitis.**—R. Clement Lucas reports three cases. The first case was that of a married man who had a severe inflammation, attacking each testicle in succession, following upon an attack of influenza. The other two cases were in boys, one aged eight, and the other three and a half years. These three cases occurred within a few weeks during the severe autumn epidemic, and suggested the idea that perhaps in certain epidemics the tendency to testicular complications may be more common than in others. The acute inflammation which occurred in the younger boy's case closely resembled the acute inflammation, with redness and oedema of the scrotum noticed in the case of the man. It was an acute inflammation of both the body and epididymis of the left testis, extending through to the scrotum, causing oedema and redness of the superficial tissues. From these cases it is concluded that inflammations of the testes may occur as the result of influenza following close upon the fever; and that after one testis has recovered the second may be attacked. When there is an epidemic of influenza in the neighborhood, sporadic cases of orchitis probably occur as the result of the influenza organism, though it may be difficult to trace the relation of the orchitis to the preceding infection.

*Münchener medicinische Wochenschrift, July 14, 1903.*

**Koplik's Spots in the Early Diagnosis of Measles.**—Aronheim, during a recent epidemic, saw at least 150 cases before the eruption had appeared. Careful examination was made for the presence of Koplik's spots, but in only nine were they found. From this it would appear that they do not occur in anything like the proportion of cases as has been supposed, and that their value in the early diagnosis of measles has been very much over-estimated.

**Protection of the Healthy Skin During the Application of the Röntgen Rays.**—G. Holzknecht and R. Grünfeld have devised a protective covering for the skin for use during the application of the Röntgen rays. It consists of a sheet of tin which is covered on both sides with a thin layer of hard rubber. The plate thus made may be of any size and shape desired and perforated by as many apertures as wished. It is very flexible and may be easily adapted to the various curvatures, etc., of the body. It is light and easy to handle, and may be sterilized, washed, or heated without damage. Its extended use shows that it affords a complete protection to the healthy skin from the burning and other annoyances which frequently attend the use of the application of the Röntgen rays.

**Aortic Regurgitation Following Traumatism.**—Th. Struppler reports a case in which an aortic regurgitation first developed four months after a severe traumatism (crushing) of the breast. It seems certain that the cardiac lesion was due to the traumatism, since previous examination had shown none to be present, and at no time had the patient suffered with any condition which might act as an etiological factor in the development of the insufficiency. The especial peculiarity of the case consists in the low tone and variable intensity of the murmur. As a rule, traumatic lesions of the aortic valves give rise to loud and constant murmurs. This, however, is not always the case, since in this patient the murmur on different days was very variable, on some being very loud, and on others scarcely appreciable, so that if auscultation were practised on the latter the heart would, in all probability, have been pronounced sound.

*Deutsche medicinische Wochenschrift, July 9, 1903.*

**Active Immunization against Pest by Means of Non-virulent Cultures.**—W. Kolle and R. Otto say that experimentally in animals much more complete and permanent immunity against pest is obtained by the inoculation of non-virulent cultures of pest bacilli than by the products of virulent cultures which have hitherto been used for this purpose. The inoculation of rats and guinea-pigs, by the authors, with such non-virulent cultures produced a complete immunity in 80 per cent. of the former and 60 per cent. of the latter animals. Furthermore this immunity was still present three months after the inoculations. For this purpose only one inoculation was practised in each animal. As will be seen, these results much excel those obtained by Haffkine and others from inoculation with the products of virulent cultures.

**Antitoxin Treatment of Diphtheria.**—W. Pulawski has treated many hundreds of cases with antitoxin with a marked reduction in mortality over all other forms of treatment. All of the fatal cases had laryngeal complications, and many also showed affections of the trachea, bronchi, or lungs. Laryngeal cases were treated successfully with great regularity, unless they first came under treatment at too late a period of the disease. Purely tonsillar cases usually run an abortive course if the inoculations are given early in the course of the disease. In none of the cases were any of the so-called antitoxin rashes observed, nor did any complications of a serous nature develop. There were no local infections at the site of the inoculations. As a rule, the most prompt results were obtained in those cases in which, in addition to the antitoxin, the ordinary medical and surgical measures, when indicated, were also used. The mortality for the laryngeal cases was 12.7 per cent.

*Berliner klinische Wochenschrift, July 13, 1903.*

**Treatment of Hay-fever with Dunbar's Antitoxin.**—Robert Immerwahr has been a sufferer with hay-fever for twenty years, and has tried the usual methods of treatment with ill success. He has recently used Dunbar's antitoxin, but did not obtain any appreciable relief therefrom. During a portion of the time that he used it the symptoms were somewhat improved, but this was during rainy and cloudy weather and without any treatment the symptoms are lessened under such conditions. It is probable that if he had remained indoors during the treatment the results would have been better, but he was forced to be continually out of doors. The direct application of the antitoxin is difficult of application and for many reasons unsatisfactory, and it is to be hoped that its subcutaneous use will soon be perfected.

**Bactericidal Action of the Radium Rays.**—R. Pfeiffer and E. Friedberger show that these rays possess but little, if any, bactericidal power, unless the radium is brought into close proximity (not over 1 cm.) with the organisms to be killed. Typhoid and cholera bacilli were the organisms which were experimented with, and these growing in nutrient media were killed or markedly inhibited when exposed to radium at the above distance for forty-eight hours. Further experimentation shows that the action is a pure bactericidal one, and that the radium had no action upon the nutrient media so as to destroy its nutrient properties. Further research is necessary in order to decide whether radium is suitable for the treatment of various bacterial cutaneous diseases, or whether its injurious effect upon the tissue cells will preclude its use in this field of medicine.

**Etiology and Specific Treatment of Autumnal Catarrh.**—Dunbar considers as autumnal catarrh that form of hay-fever which occurs in the United States during the latter part of the summer and early autumn, and which is thought to be due to the inhalation of the pollens of the golden rod and rag weed. The question arises as to whether the pollens of these plants are identical or closely related to those which produce the hay-fever common in Germany. Experimentation has shown that they are not identical, although in all probability closely related. Persons who are susceptible to the pollens of Germany vary in their susceptibility to the pollens of the golden rod and rag weed. Furthermore, those which are susceptible to both, if given the latter to inhale, show different results from the application of Dunbar's antitoxin. In some the symptoms are entirely dissipated by such antitoxin. While in others no effect is produced. No endeavors have as yet been made by the author to obtain an antitoxin for the pollens of the golden rod and rag weed on account of the small supply of the same which he possesses.

*French and Italian Journals.*

**Smallpox and Vaccination.**—J. E. Laberge, in an exhaustive article on the subject, gives the following statistics of the results of vaccination: In Westphalia, for the thirty-one years preceding the discovery of vaccination, the annual number of deaths to the million was 2,643. This has fallen to 114 for each year following. In London there used to be from three to five thousand per million; after vaccination was introduced this fell to 304, then to 149, and to 132 in 1855. In Sweden, from 1774 to 1801, the annual number of deaths per million was 1,973; from 1802 to 1806, 473; and from 1871 to 1877, when vaccination was obligatory, 189 per million. The statistics of other countries give the same results. The author strongly urges compulsory vaccination.—*L'Union Médicale du Canada*, July, 1903.

**Nycturia in Cardiovascular Affections.**—M. Péhu holds that in a large number of subacute or chronic affections characterized by temporary or permanent involvement of the heart, the normal rhythm of urinary elimination is modified, the excretion being more active at night than during the day. This symptom is found not only in diabetes and scleroses of the urinary apparatus, but also in diseases affecting the systemic or the portal circulation. It would appear to be due to insufficiency of the myocardium in eliminating fluids ingested during the day, which remain in the tissues or blood. During the repose of the night, as arterial pressure is raised, watery excretion is produced. According to this theory, nycturia is a sign of cardiac weakness and will assist in the diagnosis of insufficiency of the muscle when there is no frank asystole. The occurrence of this symptom will suggest certain methods of treatment, especially the reduction of fluids ingested.—*Revue de Médecine*, July 10, 1903.

**Malaria and Mosquitos.**—Ph. Hauser concludes that while it is proved that malaria may be transmitted from a malarial patient to a healthy individual by means of the mosquito, it has not been proved that there is no other method of transmission. Malarial germs live outside of the human body in moist soil. Malaria may exist in regions totally devoid of anopheles. The infectious germ may live in the soil in some form as yet unknown and be transmitted to man through the air, or through the mosquitos, which obtain it from the soil. The flagellate form of the plasmodium is merely the first step of the free life of the parasite. Man may become infected by drinking water in which infected mosquitos have died, or by inhaling dust from dried marshes. Blood containing the parasite may transmit malaria by means of handkerchief or other clothing stained by this blood. Infected mosquitos dying in the marshes or in stagnant water set free the hematozoon, which may transmit malaria through the air alone.—*La Médecine Moderne*, July 8, 1903.

**Constipation of Spasmodic Origin.**—M. Romme says that habitual constipation is, as a rule, due to atony of the intestines. Some cases, however, are of nervous origin, and due to a spasmodic condition of the large intestine, and it is not to be wondered at that they fail to yield to the treatment usually applied. The patient is usually neuropathic, and the condition not of long duration. The abdomen is usually found to be flattened, and not painful. The large intestine is contracted and feels like a cord. The sphincter is in a condition of permanent contraction. Treatment consists, in the first place, of warm compresses on the abdomen, renewed every hour or two, and left on for two or three days and nights. Tepid sitz baths should also be given, or, better yet, douches of tepid water on the abdomen for about two minutes at a time, applied circularly in the direction of the ascending, transverse, and descending colon, then to the legs, thorax, and back. Large intestinal douches of tepid water are also beneficial. In obstinate cases drastic purgatives are injurious. Belladonna, or opium preceded by a little castor oil, may be administered.—*Tablettes Médicales*, July 16, 1903.

**The Yellow Diazo-reaction.**—C. Gualdi says that the attention of scientists has been so far mainly directed to the red diazo-reaction of Ehrlich, and considers it strange that a fact observed by Ehrlich himself appears to have escaped their notice, namely, the yellow coloration of the foam of urine after treatment with the sulph. anilic solution and ammonia. The author's conclusions, from his observations and experimentations in regard to this point, are: that yellow diazo-reaction is found in cases of pneumonia which run a typical course and terminate by crisis; that it is also found where there is intestinal putrefaction. It is probably due to the decomposition of albumin, either in the tissues of the body or in the ingesta; yellow diazo-reaction is associated with the presence of large amounts of phenol in the urine, or of substances containing one or more phenol radicles. Certain substances given to the patient or added to the urine may simulate yellow diazo-reaction. Clinically this sign is of prognostic value in pneumonia, and is an easy method of demonstrating the presence of phenol in the urine.—*La Riforma Medica*, July 8, 1903.

**Pupillary Disorders in Tabes.**—A. Rochon-Duvigneaud and Jean Heitz state that from the examination of seventy-seven cases of tables they reach the following conclusions: (1) In 35 per cent. of the cases the pupil had retained a certain degree of reflex contraction to light, and dilatation in darkness, thus presenting an incomplete Argyll symptom. (2) Thirty per cent. showed on both sides and 13 per cent. on one side a diminution or abolishing of the contraction reflex to convergence. They had lost all reaction to light and therefore had a complicated Argyll symptom. (3) Myosis was regularly accompanied by a simple Argyll symptom—that is to say, the contraction to convergence was perfect. (4) Mydriasis was always accompanied by a complicated Argyll symptom, *i.e.* the contraction to convergence was absent or defective. Reaction to light was totally abolished. In a certain number of cases mydriasis depended on blindness. (5) If mydriasis existed with preservation of vision, accommodation was usually found to be paralyzed. There is therefore total internal ophthalmoplegia exhibited in the sphincter of the iris and the ciliary muscle. (6) In a certain number of cases, usually accompanied by mydriasis, we find a paralysis of the iris reflex to accommodation and to convergence, incident with a preservation of accommodation. The cause of this is unknown.—*Archives Générales de Médecine*, July 7, 1903.

*Annals of Surgery, May*, 1903.

**Os Trigonum Detected by the X-Rays.**—H. P. Mosely reports the case of a man aged twenty-seven years who, as the result of being struck by a falling piano, received severe injuries to the leg and ankle. On admission to hospital, the latter was swollen, tender, and œdematous. Manipulation over the tarsal bones caused pain, and there was much deep ecchymosis. No crepitus or false point of motion could be detected. A fracture of the tarsus or metatarsus was suspected, but could not be made out. Under the rays it was found that there was what was at first supposed to be a fracture of the astragalus, a portion of its posterior aspect being chipped off. Another exposure made after recovery showed the same condition, which was also found to be present in the uninjured ankle. The object giving the shadow was regarded as an os trigonum, an abnormal tarsal bone described by Bardeleben in 1883. According to Quain, it is an ossicle, due to the separation of the external tubercle on the posterior surface of the astragalus and its ossification from a distinct center.

# Book Reviews.

THE REFRACTION AND MOTILITY OF THE EYE. For Students and Practitioners. By WILLIAM NORWOOD SUTER, M.D., Assistant Surgeon Episcopal Eye, Ear, and Throat Hospital, Washington, D. C. Illustrated with 101 Engravings in the Text and 4 Plates in Colors and Monochrome. Philadelphia and New York: Lea Brothers & Co., 1903.

THE scope and character of this work has been very modestly and accurately set forth in the preface. The author has endeavored to furnish a textbook on the subjects of refraction and motility of the eye which can be readily understood by the beginner in ophthalmology and sufficiently complete to meet the requirements of advanced students and practitioners.

The work is one of 390 pages, is well printed, and is fully illustrated. It occupies a middle plane between that of the elementary works on refraction and motility and the works of Donders and Landolt. The book is divided into four parts. Part I is devoted to the theory of refraction and considers the "nature of light," the properties of lenses of all kinds, and the optical principles of ophthalmoscopy, skiascopy, and keratometry. Part II contains a discussion of the normal eye as regards its refraction and motility. Part III takes up the discussion of the errors of refraction as regards the human eye. Part IV treats of the disorders of motility of all kinds.

The work is devoid of bias, is direct and accurate, and is undoubtedly the best of its kind that has been published in recent years.

THE PRACTITIONER'S GUIDE. By J. WALTER CARR, M.D. (Lond.), F.R.C.S., Physician Royal Free Hospital; T. PICKERING PICK, F.R.C.S., Consulting Surgeon St. George's Hospital; ALBAN H. G. DORAN, F.R.C.S., Surgeon to the Samaritan Free Hospital, and ANDREW DUNCAN, B.S. (Lond.), F.R.C.S., M.R.C.P., Physician Branch Hospital Seaman's Hospital Society. London and New York: Longmans, Green & Co., 1902.

THIS work aims to present to the general practitioner condensed descriptions of disease, with especial reference to diagnosis, symptoms, and treatment. From such a point of view the labors of the editors have been admirably performed, and, in an emergency, will tend to save much precious time for the eager reader. The matter is admirably condensed and covers the discussion of all the maladies liable to be encountered by the busy medical man. The subjects are treated in alphabetical order and admit of ready and easy reference. A specially valuable feature is the detailed treatment of each affection, and the reasons for such modifications as may depend on particular conditions; and, best of all, the work, as a whole, is thoroughly practical in every particular.

THE SURGICAL TREATMENT OF GASTRIC AND DUODENAL ULCERS. By B. G. A. MOYNIHAN. New York and Philadelphia: W. B. Saunders & Co., 1903.

THIS monograph gives, in a concise form, the extensive experience of the writer in gastric surgery. Moynihan values highly the results of gastroenterostomy for chronic ulcer of the stomach. In his hands it almost always gives complete satisfaction, both to the patient and the surgeon. In all cases of gastric ulcer gastroenterostomy should be the only operation to be performed. Excision is unnecessary, often impossible, always insufficient. It therefore does not deserve commendation.

With reference to the newer means of facilitating gastroenterostomy Moynihan expresses himself as follows: "In the performance of gastroenterostomy, I have made the anastomosis on the anterior and on the posterior surface, and I have used the Murphy button and Laplace's forceps as aids to the operation. I wish to speak gratefully of the help I have received from these instruments, but the greatest service they have rendered me is to convince me that they are entirely unnecessary. No better anastomosis is possible than that made with the simple suture, none is so safe, none so adaptable, and so far as speed is concerned, I am content to abide the decision of the timekeeper. With the simple suture a gastroenterostomy rarely takes, from the beginning of the incision to the last skin suture, more than thirty minutes."

THE MEDICAL AND SURGICAL USES OF ELECTRICITY, Including the X-Ray, Finsen Light, Vibratory Therapeutics, and High-frequency Currents. By A. D. ROCKWELL, A.M., M.D. New York: E. B. Treat & Company, 1903.

THE work of Beard and Rockwell after passing through several editions was revised in 1896 by Dr. Rockwell in a very thorough manner. In again coming forward with a new edition the author has not failed to make full use of his opportunities. This is clearly shown in the six additional chapters on Vital Processes, the Finsen Light, Vibratory Therapeutics, and High-frequency Currents. The nutritional value of the current, so strongly brought out in previous editions, is again accentuated.

This work has been reviewed on former occasions with much detail. To particularize again would entail needless repetition.

Enough that the work has stood the test of long usage; that it has been increased in usefulness by the additions already adverted to; and that coming again, an old friend, mellowed by time, and set out in a new and engaging dress, it may confidently be commended as a safe and helpful guide.

SPECIELLE MUSKELPHYSIOLOGIE ODER BEWEGUNGSLEHRE. Von Dr. R. DU BOIS-REYMOND, Privatdocent in Berlin. Mit 52 Abbildungen. Berlin: August Hirschwald, 1903.

THE author puts into this volume the results of his careful study of the various phases of muscle physiology. He considers the structure of the bones, joints, and muscles. He investigates both the general and special mechanism of the muscles, and concludes with a chapter on standing and walking.

LERNEN UND LEISTEN. Rede zur Feier des Geburtstages des Kaisers und Königs in der thierärztlichen Hochschule zu Berlin gehalten am 27. Januar, 1903. Von HERMANN MUNK. Berlin: August Hirschwald, 1903.

THE writer presents this enthusiastic little monograph which is full of encouragement to the student. Its keynote is, "The more one learns, the better service he can render to his country."

GOLDEN RULES OF REFRACTION. By ERNEST E. MADDOX, M.D., F.R.C.S., Ed. Oph. Surg. Royal Victoria Hospital, Bournemouth; late Asst. Ophth. Surg. Royal Infirmary, Edinburgh, and Syme Surg. Fell. Edinburgh University. "Golden Rules" Series, No. XII. Bristol: John Wright & Co.; London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd., 1903.

THIS little work contains many of the essentials of refraction given in a very elementary form, and may be of some service to the general practitioner and to the student, principally as a stimulus to the acquirement of a greater knowledge of this important subject.

PETITE CHIRURGIE PRATIQUE. Par TH. TUFFIER et P. DESPOSSES. Paris: C. Naud, 1903.

THE teaching of minor surgery to medical students has been incomplete in most of our schools. The principles of asepsis and antisepsis, the method of administration of anæsthetics, the treatment of fractures, and the technique for the performance of minor surgical operations are most important for the young physician who is to enter active practice without the advantages of a hospital training. Tuffier has in this excellent book afforded to nurses much needed information for the care of the sick and wounded, and to students and practitioners a clear, concise exposition of the principles of minor surgery, including bandaging, anæsthesia, the treatment of fractures, and the like. The book is well illustrated, and well edited and printed.

DISEASES OF THE LIVER, PANCREAS, AND SUPRARENAL CAPSULES. By LEOPOLD OSER, M.D., Professor of Internal Medicine, University of Vienna; EDMUND NEUSSER, M.D., Professor of Internal Medicine, University of Vienna; HEINRICH QUINCKE, M.D., Professor of the Practice of Medicine, University of Kiel; G. HOPPE-SEYLER, M.D., Professor of Internal Medicine, University of Kiel. Edited with additions by REGINALD H. FITZ, M.D., Hersey Professor of the Theory and Practice of Physic, Harvard University, and FREDERICK A. PACKARD, M.D., Late Physician to the Pennsylvania Hospital and to the Children's Hospital, Philadelphia. Authorized translation from the German, under the editorial supervision of ALFRED STENGEL, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Philadelphia, New York, London: W. B. Saunders & Co., 1903.

THE first portion of this volume treats of the diseases of the pancreas, taking up the latest known facts with regard to this little understood organ. The author has incorporated the essentials of Korte's and Mayo Robson's work, to which the editor has added the latest information of Opie and of Flexner, some of which appeared since the issue of the original German text.

The section on the diseases of the Suprarenal Glands, written by E. Neusser of Vienna, gives in a concentrated form what is known about these organs and their internal secretion. The main part of the book is apportioned to the disorders of the liver. Dr Hoppe-Seyler and Dr. H. Quincke of Kiel have done full justice to their task, and have produced a piece of work which will long remain an authority on the diseases of this viscus. The physiology, anatomy, deformities, pathology, etc., are all sufficiently complete while the portions appertaining to diagnosis and treatment will commend themselves to the clinician as being the outcome of ripe experience and close observation.

SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, Held April 23, 1903.*

L. J. LADINSKI, M.D., CHAIRMAN.

**Nephropexy for Movable Horseshoe Kidney.**—Dr. ARNOLD STURMDORF reported this case. He said that, according to Henry Morris, horseshoe kidney occurred once in 1,600 cases, and the rather extensive literature on nephropexy that had accumulated since Hahn's first publication in 1881 did not contain a single reference to this anomaly. His patient was an Italian woman, who had been referred to him through the courtesy of Dr. A. Morani. She had been married eight years, was the mother of three children, and had never aborted. There was nothing in the previous history bearing upon the condition. She complained of a dragging sensation in the lower dorsal and upper lumbar spine with constant pain of varying intensity radiating from this area downward and forward toward the lower abdomen. The pain and dragging would subside when the patient assumed a recumbent posture, but she was never entirely free from discomfort in the back and right side of the abdomen. These symptoms had first appeared two years ago after an instrumental delivery, and since that time had gradually become more severe until they had finally incapacitated her for household duties. Several times during the past seven months she had experienced sudden exacerbations of the pain during which complete anuria had occurred, followed after a variable period by a copious polyuria with partial abatement of all the symptoms. The patient had lost both weight and strength. When examined on February 2, 1903, it was noted that she was a pale and slender woman, but without any apparent abnormality of the bodily functions, with the exception of the urinary fluctuations referred to. Palpation revealed a hard and smooth solid mass occupying the right side of the abdomen and seeming to fill the right loin. It could be freely moved up and down and slightly from side to side. Its lower pole was on a level with a line connecting the two anterior superior spinous processes. It extended anteriorly to a continuation of the parasternal line. The lower end of the mass was indefinitely rounded, and the upper end reached under the ribs and could not be palpated. The right margin was rounded and well defined; the left was irregular and depressed. It did not appear to have the shape of the kidney, and although distinctly movable in an upward direction, it could not be made to slip into position on bimanual pressure in the manner so characteristic of a floating kidney. Its post-peritoneal origin was demonstrated by colonic inflation. The right renal region showed a depression below the ribs posteriorly. The urine was normal. The left kidney was not palpable, and the rest of the examination was negative. On February 10 a dorsal oblique incision was made from the last rib to the iliac crest. The upper pole of the kidney presented in the depths of the wound, and was readily liberated, but the lower pole could not be isolated because of its projection inward beyond the reach of the finger. The peritoneum along the outer border of the kidney was then incised, and this exposed a perfectly characteristic, mobile horseshoe kidney. The kidney could not be delivered sufficiently to allow of the use of the author's capsular flap formation, and accordingly the Senn method of gauze packing was resorted to. This gave firm anchorage and complete relief to the patient, who had entirely recovered at the end of three weeks. The speaker remarked that this could not be properly classed as a floating horseshoe kidney, inasmuch as the right segment was movable to a marked degree independently of the left; it was more probably a congenitally displaced horseshoe kidney, the right half of which had become detached in some manner

**Hysterectomy for Subperitoneal and Submucous Fibroids.** Dr. AUGUSTIN H. GOELET presented specimens from a case of this kind.

**Hysterectomy for Chronic Metritis and Uncontrollable Hemorrhage.**—Dr. BROOKS H. WELLS reported this case.

**Large Polycystic Kidney; Operation.**—Dr. WELLS also showed a large polycystic kidney, removed by operation in June, 1902, from a young woman sent to him by Dr. Hetzel of Southport, Conn. She complained of general malaise, a dragging sensation, and a constant dull pain, increasing in severity. These symptoms represented the pressure effects of a slowly growing oval tumor occupying the right side of the abdomen and extending from under the ribs to two inches below the umbilicus. It was rounded, nodular, slightly movable, and sensitive. The kidney on the left side was apparently normal, as was also the urine. The patient's general condition was good. A diagnosis of tumor of the kidney, probably cystic, was made, and on June 10 the usual incision along the outer edge of the quadratus lumborum muscle was made in an attempt to remove the tumor. The tumor was enucleated and removed, and the wound was closed without drainage. The patient made a quick recovery, there being very little shock and no fever or urinary disturbance. The speaker said that he had waited ten months before reporting this case, because surgeons, as a rule, advised against removal of a large polycystic kidney on the ground that the disease was usually bilateral, and even if a fatal anuria did not rapidly supervene, the other kidney was liable rapidly to develop the same cystic condition. He believed, however, that in the rare instances, like the one just reported, in which there was good reason to believe that the disease was unilateral, and the tumor was causing distress, surgical intervention was justifiable, and that life was likely to be prolonged by the removal of the diseased kidney. At the present time his patient appeared to be perfectly well, and she had been completely relieved of her former symptoms.

**Surgical Kidney, Probably Tuberculous.**—Dr. WELLS also presented this specimen, which had been removed from a man of twenty-three. Six years ago he had suffered from gonorrhœa, and had been treated for it for one year. In April, 1901, he had been treated by a physician for gleet and stricture, sounds being passed frequently into the bladder. During this period he suffered repeatedly from what he called chills and fever, as well as from pain and stiffness in the right lumbar region. He then applied to Dr. Beyea of New Rochelle, who found fluctuation over the quadratus lumborum muscle on that side, and evacuated pus. The incision closed after three weeks, but the patient continuing to fail, he was referred to Dr. Wells in July. His appearance at that time was decidedly septic, and the urine contained blood, numerous granular and epithelial casts and a large quantity of albumin. There was no tenderness or tumor over the region of the right kidney, gall-bladder, or appendix, but there was pouting red area an inch above the ilium and about an inch and a half from the median line on the right side. Under ether this was incised, and the fistulous tract followed down to the kidney, resulting in the evacuation of about ten ounces of creamy pus. The wound was packed and drained. Convalescence was slow, and the wound did not heal completely for three months. The kidney felt rather hard to the touch, but because of the existing local and general conditions, it was not incised. The patient's general condition and the urine improved slowly after this operation, but last January the patient began again to complain of dull pain in the right loin and of general malaise, and there was a discharge of a few drops of watery pus from the upper angle of the old wound. An *x*-ray photograph of the right loin showed a faint opacity over the area of the kidney. On February 18 the kidney was removed through the usual loin incision, and the wound

was closed, except for a small cigarette drain. The patient made a rapid convalescence and improved in color and strength, and the urine became normal except for an occasional pus cell. On incision of the kidney the parenchyma was found to have entirely disappeared, the capsule being filled with a mass of inspissated pus resembling mortar.

**Abdominal Hysterectomy for Myofibromatous Uteri.**—Dr. H. J. BOLDT presented a number of specimens. The first specimen was one of pan-hysterectomy. The cervix was very short and one fibroid was of the intraligamentous variety. The patient, a nulliparous woman of thirty-two, had suffered several years from pressure symptoms in the left lower abdomen, associated with lancinating pains radiating down the entire lower extremity. At times there was œdema of the leg. There was menorrhagia but no metrorrhagia. The opeation presented the difficulties usually met with in this class of tumors, but recovery was uninterrupted.

The second case was one of supravaginal amputation, done in a virgin of thirty-six, who had suffered from numerous attacks of metrorrhagia, and had had menorrhagia for a number of years. At times there were present intense bearing down pain in the abdomen and severe backache. The large submucous tumor had a broad and inseparable base with the uterus proper, so that it formed a part of that organ. Because of the anæmic condition of the patient, 1500 c.c. of saline solution were injected into the median basilic vein before the operation was commenced, a procedure always to be recommended where there was extreme anæmia. Recovery was uneventful.

**Small Spindle-cell Sarcoma of the Ovary and Liver.**—The interesting feature here was that the enormous liver filled the abdomen so complet ly, and at one part was directly attached to the ovarian tumor, so that, on palpation, the tumor was thought to be entirely of ovarian origin, there being no space between the neoplasms. The tumor that filled the pelvis palpably contained fluid, whereas the abdominal part of the tumor was unquestionably solid, and the nodular condition of the solid tumor, associated with ascites and cachexia, led to the diagnosis of sarcoma of the ovary. It was thought that the liver was crowded up under the diaphragm. The specimens showed clearly that a differential diagnosis was impossible. The true condition did not become apparent until the hand was placed at the summit of the tumor to dislodge it, when it was found that the liver formed the tumor. The sarcoma of the ovary was removed because of hemorrhage from adhesions to the liver. Dr. H. T. Brooks, as the result of his examination, believed the ovarian sarcoma to be the primary tumor.

**Tubal Abortion; Profuse Intraperitoneal Hemorrhage, No Formation of a Hæmatocele.**—The patient had given birth to her last child nineteen months ago, and had been nursing the infant up to two months ago. Her menstruation had been regular for several months until the last period, when she went eight days overtime. For two weeks she had irregular spotting. On April 20 she had intense pain of a cramp-like character in the right iliac region, radiating over the entire lower abdomen. The physicians called in made a probable diagnosis of perityphlitis, or of appendicitis. At that time she began to bleed more profusely, but it was thought to be the regular menstrual flow. Examination the following day revealed a thickening of the right Fallopian tube near the abdominal extremity to about four times its normal dimensions, and a swelling sensitive to the slightest touch. There was an indefinite fulness in the cul-de-sac, as though fluid was present in it. There was no evidence of a formed hæmatocele. Appendicitis was excluded absolutely. The diagnosis of progressing tubal abortion was made, and in view of the fact that there was no apparent tendency of the blood to coagulate, operation was advised. The abdomen was found very full of blood at the time of operation, and the patient was almost pulseless, so that an intravenous infusion of 1,800 c.c. was given. Bleeding from the fimbria was still present. A large quantity of saline solution was left in the abdomen. Convalescence was now progressing satisfactorily.

**Ovarian Cystoma; Three Twists of the Pedicle from Left to Right.**—The patient had been aware of the presence of an ovarian tumor for about eighteen months, but had been informed by her physician that medicine would cure her. Two days before she was seen by Dr. Boldt she felt the pain, which had been present about two weeks in the lower abdomen increase, greatly in intensity, so that even ice-bags and opiates gave no relief. Examination showed diffuse peritonitis at the time when seen. The diagnosis of a right ovarian tumor with twisted pedicle was readily made, and, in view of the peritonitis, she was at once removed and operated upon. The tumor was found to be gangrenous; many adhesions were present, and a considerable quantity of blood-stained ascites. The right Fallopian tube was greatly distended with blood, and blood was oozing from the fimbriated extremity at the time. An acute appendicitis was associated with the condition, probably as a result of an extension of the inflammation. Recovery was progressing satisfactorily.

**Cancer of the Uterus; Vaginal Hysterectomy; Recovery.**—The patient, forty-two years old, had been bleeding irregularly for two months. Examination showed that a malignant neoplasm involved the entire cervix. Although she had consulted her family physician about the bleeding, no examination had been made, ergot and hydrastis seemingly having been relied upon to control the bleeding. Although gynecologists had often insisted that, in all instances of atypical bleeding, one must suspect malignant disease, and a positive exclusion of such change must be made before internal remedies were used to control the bleeding, this teaching did not seem to have found a general foothold.

**Surgical Kidney; Nephrectomy.**—The patient had been seen for the first time thirteen months ago, at which time a diagnosis of pyelitis had been recorded. She had not been seen again until a few days ago, when she entered the hospital for operation, the pain in the right loin having become constant. The kidney was large and, as a result of inflammatory changes all around it, was exposed with great difficulty. Two stones were felt in the organ, and an attempt was made to save the organ, but while endeavoring to dislodge the kidney one abscess was torn into, and the structure somewhat mutilated. It was then thought best to remove it. Several abscess cavities were found in the kidney, and four stones were imbedded in the pelvis. The ureter was thickened considerably, but was not much dilated. Convalescence was progressing satisfactorily.

**Abdominal Hystero-salpingo-oophorectomy.**—The patient had had a ventral suspension done by Dr. Boldt about six months previously, and the appendix, which was the seat of catarrhal inflammation, had been removed at the time. Several cysts in the ovaries were treated with a Paquelin cautery. An abdominal-wall abscess followed, and a sinus, which went into the pelvis, had been present since the operation. At times there had been metrorrhagia. To cure the sinus, the old abdominal scar was incised four weeks ago, and the sinus thoroughly curetted. The adnexa at that time were seemingly in good condition. A week later an examination showed the right adnexa to be the seat of an abscess, probably ovarian, and the left showed evidence of inflammation. The sinus itself proved to be incurable. In view of the existing tubo-ovarian inflammation, which on the right side was suppurative, the operation as done was determined upon by request of the patient. The vaginal operation was not sidered safe because of the dense intestinal adhesions supposed to be present, and the abdominal section proved the wisdom of the course pursued. The intestinal adhesions were very extensive, and so firm that in places it

was necessary to divide them with scissors. It was likely that the suppurative process was tuberculous, but the examination had not yet been completed. The woman was doing well.

**Possible Malignant Disease of the Colon and Stomach.**—Dr. L. J. LADINSKI exhibited the specimen removed from the patient presented by him to the section at the last meeting. It consisted of a portion of the colon and a portion of the anterior wall of the stomach and of the abdominal wall. So far as the microscopical examination had gone the results were not decisive as to the presence of malignant disease. On making the abdominal incision the indefinite tumor was found to consist of a matting together of the anterior wall of the stomach, the transverse colon, the greater omentum, and the abdominal wall. The incision of the abdominal wall entered the colon. This diseased portion of the colon was removed, and the tumor was separated from the abdominal wall. A button was inserted. The entire stomach appeared to be involved quite deeply. The colon had not healed thoroughly, and if the disease were not malignant he expected to do a lateral anastomosis.

Dr. BOLDT, referring to the uterus presented by Dr. Wells, said that the appearance was such as to indicate to him that there had been originally a septic infection.

Dr. STURMDORF said that the use of the curette in these cases of persistent uterine hemorrhage was going out of vogue because experience had shown that the curette often gave only temporary relief. Recent studies indicated that the hemorrhage was due to a degeneration of the musculature of the uterus, and that the uterine muscle was in constant action, not only in pregnancy, but at other times. These facts threw light on cases of what had in the past been considered to be inexplicable hemorrhage. The curette should be limited to the cases in which a cause for the hemorrhage could be distinctly found, as, for example, the presence of a fungous endometritis.

He had been deeply interested in the kidney presented by Dr. Wells. He understood that the infection was an ascending one from the passage of sounds, yet from the appearance of the specimen he was disposed to think that it was a tuberculous kidney. The deposits present were not those from the urine, but rather those found in connection with tuberculosis of the lungs.

Dr. WELLS replied that the pathologist, Dr. Jeffries, had reported that there were no tubercle bacilli present and that the material was gritty and crystalline.

**Secondary or Repeated Laparotomy.**—Dr. HENRY C. COE was the author of this paper. He said that secondary operations were doubtless less frequent than in the early days of imperfect aseptic technique, but there was still much room for improvement, as shown by the fact that a number of patients still required a secondary laparotomy before being restored to health. Exudates, fistulæ, newly-developed neoplasms, ectopic gestation were common conditions for which a secondary laparotomy was demanded. One experimenter had made the statement that adhesions followed whenever the abdominal cavity was opened, but clinical experience was opposed to this view. Nevertheless adhesions did occur in spite of the most painstaking efforts to prevent them. Secondary pus foci might be an evidence of imperfect technique, unwise conservatism, or secondary infection. It was a common experience with the abdominal surgeon to see an apparently insignificant cystoma of the ovary, left undisturbed at the first operation, grow to such an extent as to require subsequent removal. Personal experience led him to consider it necessary to remove both ovaries in cases in which only one appeared to be the seat of papilloma. The abdominal route was preferred by him for conservative work. He had invariably endeavored to preserve the function of menstruation whenever the ovary could be safely retained, but he was beginning to doubt the wisdom of the surgeon's allowing himself to be hampered by promises to preserve portions of these organs. He was strongly averse to resection of the tubes and ovaries in pus cases. The most promising cases often proved ultimately to be the most disappointing. In at least a dozen cases he had been obliged to remove the uterus for profuse hemorrhage which did not yield to curettement, and serial sections of these uteri appeared to indicate that the cause was situated outside of this organ, Not a few of the secondary laparotomies at the present day were performed upon patients in whom at first so-called conservative surgery had been practised. There was a strong argument in favor of removing the appendix whenever it became necessary to open the abdomen for other conditions. Dysmenorrhœa, menorrhagia, and gastrointestinal disturbances might be so severe as to require surgical relief, but pain was usually the cause which made the patient seek a second laparotomy. The pain might be general or localized, and might be entirely out of proportion to the lesion. Limitation of the peristaltic movement of the bowel was often responsible for this severe pain. Why this pain should exist in some apparently insignificant adhesions and be absent when the coils of intestine were extensively matted together was difficult to say, although no doubt the neurotic element played an important part. Hemorrhages so profuse as to eventually sap the vitality of the patient frequently called for the removal of the uterus. He had met with this phenomena in connection with atrophied ovaries and where no satisfactory explanation could be given. Attention had been called to the effect of traction on the stomach in causing obstinate vomiting of other gastrointestinal disturbance.

In order to draw a correct inference as to the nature of the lesion calling for a secondary laparotomy one should have an exact history of the case, including a good description of the former operation; yet this very essential element in the diagnosis was very frequently entirely lacking among hospital patients. The presence of intestinal lesions might be inferred from a history of more or less constant colicky pains in the lower part of the abdomen. Examination under anæsthesia was advisable in doubtful cases, especially neurotic subjects. When the probable cause of the trouble was more or less extensive adhesions, one should be careful not to promise relief, for the result was always extremely problematical. While all agreed that pus sacs were best treated through the vagina, he still felt that firm adhesions above the pelvis could hardly be satisfactorily treated except by the abdominal route.

**Gynecological Surgery and True Surgery.**—Dr. EGBERT H. GRANDIN opened the discussion. He said that he was beginning to reopen the abdominal cavity for the simple reason that some years ago he either had not done enough or had attempted to save too much; in other words, because he had practised what he believed was wrongly called "conservative surgery." The pus cases were the ones most frequently coming for secondary operation. The avoidance of injury to the parietal peritoneum at the time of the first abdominal section through the use of sharp retractors he would pass by, although admitting that it was a frequent source of adhesions and of subsequent pain. The same might be said about the use of silk and non-absorbable suture material. One of the chief causes of secondary operation was the fact that we did not yet know how to repair the damage done in the pelvis by an exceedingly difficult salpingo-oophorectomy with the leaving behind of a raw surface. It was not the surgeon's fault that such raw surfaces were left, but one should strive to improve the technique. He did not think that the leaving of saline solution in the abdominal cavity would be of much service. It was possible that Cargile membrane, recommended by Dr. Robert T. Morris, might prove useful, although he had not yet tried it. One excellent plan was the use of gauze to keep the intestines up in place until retained by plastic exudate. When, because of pelvic peritonitis, it became necessary

to remove both tubes and ovaries, this should be done most thoroughly, including the removal of the uterus. He believed that when gonorrhœal infection once passed the internal os the woman remained infected for the rest of her days. He wished to embrace this opportunity to protest once more against what had been miscalled conservative surgery on the tubes and ovaries. It had been claimed that 10 per cent. of the patients so treated had conceived, but he would like to ask what had become of the other 90 per cent. These women came for relief of pain, and would not be satisfied with anything short of this, for the chief function of a married woman was not the bearing of children. There had been a great deal of nonsensical and sentimental talk on this subject. There was a vast difference between the ovarian secretion emanating from a normal ovary and that from a deceased ovary; just as well might the surgeon leave a piece of the thyroid in because he thought it was well to maintain the influence of the thyroid secretion. His desire certainly was to be thoroughly conservative, but it was his desire, as well as that of his patients, to conduct the treatment in such a way as to secure the needed relief. He did not wish to be accused of not being in sympathy with every method which would retain to the woman one of the essential parts of her organism, but he was now getting tired of re-operating upon cases of his own, and on those of his colleagues, because of these attempts at gynecological surgery in contradistinction to true surgery. In his opinion, there was a vast difference between these two kinds of surgery.

**Motherhood Worth Preserving.**—Dr. J. RIDDLE GOFFE, said that the most serious of the secondary laparotomies, according to his experience, were those done for fecal fistula. Next to these came cases of ventral hernia following laparotomy, and of long standing and large size. He had formerly been inclined to postpone secondary operation because of pain, supposedly the result of adhesions, but growing experience had led him to believe that these patients were not hysterical, but were actually suffering from peritoneal adhesions between coils of intestine or diseased remains of organs. He believed that when these adhesions were serious they were almost invariably due to sepsis. Adhesions from the packing of iodoform or other gauze in the pelvis he found were reabsorbed. In his vaginal work it was his custom to keep the intestine out of the true pelvis by filling the latter full of gauze, yet no serious adhesions resulted from this practice. He thought the preceding speaker had presented some very broad generalizations, and had based them upon insufficient grounds. No figures had been quoted, and much had been left to the imagination. If there were so many patients demanding secondary operations as appeared from this gentleman's remark, then the most rational conclusion was that the attempts at conservative work had been ill judged. He had himself operated in a conservative manner in a large number of cases, and yet only one of these patients had demanded surgical interference subsequently. In that case no difficulty had been experienced in passing through the adhesions. He found one tube almost completely buried in adhesions, and it was necessary to remove this tube because it was injured during the manipulations incident to the separation of the adhesions. Both ovaries and one tube were left. Dr. Coe had made the statement that, in his experience, about 5 per cent. of the cases subjected to this conservative surgery came back for secondary operations. Personally he felt that if even 20 per cent. returned he would be justified in continuing earnestly to practise this conservative work. Dr. Grandin had spoken quite contemptuously about preserving motherhood, but it was a subject in which, the speaker said, he and many of his patients felt a deep interest. He believed that unless there was very positive disease of the ovary, it was better to leave it alone than to puncture and cauterize cysts.

Dr. E. E. TULL said that by conservative surgery he understood doing only what was necessary at the time. He thought if pain had a definite pathological basis, one would not hear so much of the wonderful achievements of Christian Science. Laparotomies were often done on patients who claimed to be suffering intense pain, and yet nothing could be found at the operation to explain this pain, which was, apparently, purely psychical. He was an ardent believer in conservative surgery, and he would favor the leaving in of the uterus in many cases, and adopting every possible method of saving parts not hopelessly diseased. When ther was pus on one side, of course, the adnexa on that side should be removed, but it had not been his habit to disturb the other side unless it was also diseased. It was not a matter of indifference to the woman whether or not the menopause be artificially induced. Two years ago he had a collection of twenty babies that had been born to women upon whom he had operated, removing one ovary, although there had been some doubt about the wisdom of removing the other one.

Dr. A. PALMER DUDLEY said he wished to avail himself of the friendly challenge that had been thrown down by one of the previous speakers. The time had gone by for the hysterectomy to be the only panacea for woman's ills. That was true of the nineteenth century, but we were now in the twentieth century, and advances were being constantly made. He believed there would be very few who would be willing to sacrifice the testicle, the seat of a gonorrhœal orchitis, and it seemed only right to give the woman the same consideration and choice. It was true that secondary laparotomies were sometimes demanded after conservative surgery, but he had not met with any woman who was sorry that this attempt at conservatism had been made, whereas he had met with many women who were deeply resentful, because everything had been ruthlessly removed at the first operation. The same influences which produced the disease in the first place often continued, and so explained the necessity for a subsequent operation. He purposed to publish in a short time statistics which, he thought, would thoroughly prove the correctness of his position with regard to this conservative surgery.

Dr. H. L. COLLYER said that it was only about ten years ago that healthy ovaries and tubes were presented to this section with the statement that the cases were examples of catarrhal salpingitis; but surgery was advancing and laparotomy, might be done repeatedly, each time for a different diseased condition. Even women who had had healthy ovaries and tubes removed by operation, suffered from pain after the operation In his opinion, this agitation of the subject did more harm than good, because the general profession gained the impression that when a woman suffered from abdominal pain everything must come out.

Dr. PHILANDER A. HARRIS said that when the tube became infected it was a sinus, and an infective inflammation therein must necessarily be very chronic. The ovary was entirely different in structure from the tube, and he believed it was an unwilling participant in inflammation; consequently 90 per cent. of all women upon whom he had operated in the past four years by suprapubic section for pus tubes continued to menstruate, and did this quite regularly. There had been no amputations of tubes; the latter had been taken out to the uterine mucosa. The ovary should certainly not come out because the tube was diseased, unless it was the seat of abscess.

Dr. L. J. LADINSKI said he desired to emphasize the treatment of the appendix in operating upon the pelvic organs, and he would like to hear Dr. Coe's opinion on this point. Some months ago he had presented to the section a woman upon whom two laparotomies had been done in two years for tumors of the ovary. She had come to him last year with pus in the urine and pain on the right side, and begging for a laparotomy. She was kept under observation for a month, during which time the urinary

symptoms disappeared. Being convinced that she had pain, he finally decided to do an exploratory laparotomy. Under anæsthesia he could feel the appendix very distinctly. Laparotomy disclosed the tip of the appendix adherent to the stump of the right pedicle of the tube and ovary, the appendix itself not being diseased, although it was kinked from lying over the brim of the pelvis. This had given rise to an appendicitis. The appendix was removed, and the patient made a good recovery.

Dr Cob, in closing the discussion, said he was sorry that Dr. Grandin was unfortunately not present, yet he wished to reply to some of his statements. In the first place, he would object to the way in which the term gynecological surgery had been employed, for, personally, he looked upon it, not as a term of reproach, but as one of honor. No doubt many of the poor results were due to imperfect technique. He certainly would not resort to a secondary laparotomy unless the patient had been for a considerable time under observation, and he was satisfied that there was real ground for the patient's complaints. He could not agree with Dr. Harris regarding the advisability of practising conservative surgery after the plan he had described. The main object of conservatism in this field was to conserve the function of menstruation. He could recall eight or ten cases in which the appendix had been thickened, diseased or adherent, and his own practice was to remove the appendix in every case in which the abdomen was opened for other causes.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON PEDIATRICS.

*Stated Meeting, Held May 14, 1903.*

HENRY HEINMAN, M.D., CHAIRMAN.

**Case of Mongolian Idiocy.** — Dr. HENRY HEINMAN presented a child of ten months with Mongolian idiocy. This type, he said, was between the cretin and the true idiot, and was called cretinoid. The posterior fontanelle was still open, there was a lateral nystagmus, and the eyes were almond-shaped. The liver was enlarged, extending half a finger's breadth below the free border of the ribs. The spleen was not enlarged. The child weighed ten pounds and ten ounces, and showed marked impairment in psychical development. There was also lateral displacement of the digits. A great many cases of Mongolian idiocy had the little finger curved toward the middle finger. The oblique eye differed from that of true cretinism. The skull was of the brachiocephalic type. The tips of the fingers were pointed, and the ears presented the type of degeneracy. The mother said that this was her sixth child, and that it was different from any of the previous children.

Dr. L. E. LA FETRA remarked that many children had the Mongolian type of face without the other symptoms being present.

Dr. H. W. BERG asked on what the diagnosis of psychical defect rested.

Dr. HEIMAN replied that if one tried to play with the baby and attract its attention by a watch, it would be found not to notice as soon as would a normal infant in seven months. When a number of children were asked the nationality of this child they said it was a Chinese baby. The treatment had consisted in the administration of thyroid extract, half a grain, three times a day. Experience had shown that this drug gave little if any result, yet it was our duty to try it. In the event of failure, anti-syphilitic treatment should be employed, and the accompanying rachitis should also be treated.

**Pyloric Stenosis in Infants.**—Dr. J. G. WILLIAM GREEFF read this paper. He said that pyloric stenosis was a rare disease. Some writers regarded it as congenital, but out of thirty cases in infants, which he had found, the conclusion had been reached that the disease was an acquired condition. Myer had reported thirty-one cases in the adult, but, as a matter of fact, nothing was definitely known concerning the origin of this condition. It was probable that in pyloric stenosis some family tendency was the cause of the hypertrophy. The symptoms were very similar to those of chronic gastric catarrh, or gastritis, vomiting being the most constant. Tuberculosis and syphilis might have something to do with it, but of this nothing was definitely known. The macroscopical findings were always an increase in the circular muscle of the stomach.

After reviewing the literature, Dr. Greeff reported the following case: The subject was a male child, born last November, after a normal labor. For about two weeks the child did well. After the fourth day he was put on the bottle, receiving one part milk and two parts water. The case had first come under the speaker's observation when the child was twenty-three days old. The stools and urine were scanty, but the vomiting was almost constant. The child was poorly nourished. The lungs and heart were normal. The stomach was enlarged, extending three fingers' breadth below the umbilicus. The bowels were flushed out by calomel, the stomach was washed out, and the bowel was irrigated. The stomach washings were very sour, and contained no bile or free hydrochloric acid. The body temperature was about 102° F., but this was reduced by the irrigations. A wet nurse was procured, and the child took the breast eagerly, but vomited soon afterward. It weighed at birth eight and one-half pounds, and kept this weight for two weeks, after which it slowly lost weight. The diagnosis of pyloric stenosis was confirmed by Dr. Holt, who advised operation. Dr. Bull operated, doing a gastroenterostomy, but the child died. The stomach measured 12 cm. in length by 7.5 cm. between the greater and lesser curvatures. The stomach wall was hypertrophied, and the mucous membrane was much thickened at the pylorus. The epithelium showed a cloudy swelling, and the fibrous connective tissue contained inflammatory corpuscles, together with a general œdematous condition. When this case was first seen, all the symptoms pointed to a severe gastroenteritis. All of the reported cases of pyloric stenosis showed an absence of free hydrochloric acid. The prognosis was grave. If they did not respond to palliative treatment after a week or ten days, an operation was imperative. As to the question of what operation was an important one, Dr. Greeff said that pyloroplasty gave very good results, better than the operation of gastroenterostomy. The treatment consisted in leaving off all food by mouth for two or three days, and giving antifermentatives. The fact that this child had been able to take food at first tended to show that this condition was not congenital, but resulted from some condition developing during the last weeks of its life. The speaker suggested that some chemical influence, partly from the stomach and partly from the food, might play an important part in the causation of this disease.

Dr. A. ERNEST GALLANT showed a specimen of a child's stomach exhibiting the same characters, and taken from a case having a very similar history to the one just reported. That child had done well for two weeks, and then had begun to vomit. In the course of a week or ten days, when first seen by him, vomiting was the chief symptom. When the stomach was well emptied, the child would go to sleep for eight or ten hours. When thirty-three days old it was doing well, but, suddenly becoming worse, an operation was done. He found a contraction at the caput coli, which he thought was due to the enemas given. The stomach showed a marked thickening of the pylorus, together with a hypertrophy and puckering of the gastric mucous membrane. He was able to pass a small probe through the pylorus. The child died six hours after the operation. The speaker objected to the term "stenosis," believing that "contraction" was more nearly correct. With regard to the question of this condition being a congenital one, he said that

two weeks seemed a very short time for such an amount of thickening to take place; it was more probable that it had begun during intrauterine life.

Dr. Sara Welt-Kakels said that the disease under discussion was a very rare one. Two such cases, however, had recently been reported in the *Lancet*. It was a simple operation to cut through the sphincter in a longitudinal direction and remove the reduplication of the gastric mucous membrane.

Dr. Greefe, in closing the discussion, said that he believed this disease was not congenital, and that it was perfectly possible for the stomach to acquire that degree of hypertrophy in a short time. As to operative treatment, two cases had been successful, but usually this treatment failed. Personally, he believed a number of these cases could be cured without operation.

**Chronic Post-diphtheritic Laryngeal Stenosis as a Cause of Persistent Intubation of the Larynx.**—Dr. Henry W. Berg read this paper. (See p. 161.)

Dr. John Rogers, Jr., opened the discussion. He said that he had treated altogether fifteen cases of chronic intubation, and he differed with the writer of the paper in regard to operation. He had tried laryngotomy several times, but had given it up. One case was cited in which there was sloughing of the cricoid cartilage. By inserting a longer tube, the child got well. He believed every one of these cases was curable, but all of them required a little perseverance. In chronic stenosis of the larynx a metallic tube should never be used. In cases of autoextubation, tracheotomy should be immediately performed, and then, after two or three weeks, a tube could be introduced.

Dr. Stanton said that he had treated a number of these cases and had not lost one, but the longest time a tube had been worn was three months. That case had been intubated twelve times in this period. Perseverance was certainly essential to the successful treatment of such cases.

Dr. A. A. Berg said that stenosis of the larynx, due to cicatricial tissue, required dilatation, and when this firm, hard tissue closed down, it must be excised and the lost tissue replaced by mucous membrane of skin. When suppuration occurred, incision and drainage were demanded.

Dr H W. Berg closed the discussion. He said that he was surprised to hear Dr. Rogers advise tracheotomy in cases of autoextubation. Such cases were quite frequent in the Willard Parker Hospital, yet he would not recommend tracheotomy except as a last resort.

**Vulvovaginitis in Little Girls: A Clinical Study of 190 Cases.**—Dr. Sara Welt-Kakels read this paper. The cases were collected from the children's clinic of the Mount Sinai Hospital, where she had treated 11,000 cases. Of this number, 1.6 per cent. were gonorrhœal. The greater number of cases were between two and ten years of age A small number had a simple catarrhal vaginitis, but the majority were gonorrhœal In a few instances there were erosions of the vagina with excoriations of the perineum and inner sides of the thighs. The vagina was invariably inflamed, and the inguinal glands were enlarged and painful, but in not a single instance did these glands suppurate Most of the little patients had pain on walking and painful urination She believed most of these cases were the result of an indirect infection, as, for example by sleeping with a mother who had a "discharge" or by handling soiled bed linen and towels. Mention was made of one family in which the mother and two daughters had gonorrhœa One child contracted gonorrhœa while in the kindergarten In three cases the mucous membrane was adherent to the labia Another child of eight years had acquired syphilis One case of pediculosis of the vulva had been encountered The incubation period of gonorrhœa in children was thought by the speaker to be three or four days a much shorter period than in adults Cultures should be taken from all cases having a vaginal discharge and these should be examined by the Gram method but a negative result did not prove that gonorrhœa was not present. Repeated cultures should be taken. Formerly gonorrhœa was supposed to be a superficial infection, but it was now known to be more deeply seated, the gonococci even being found in the blood. The speaker said that she had seen one case of ophthalmia, apparently of a most benign character. This one case was cured. One case of acute gonorrhœal peritonitis was reported in which there were rigidity of the abdominal wall and general pain. An operation was performed, but the child died. Cultures from the peritoneal exudate showed the presence of gonococci. The discharge of vulvovaginitis was serous at first, and then became thick, greenish, and purulent. Holt gave the duration of this condition as from one to six months; other writers gave it as from three to six weeks. Judging from her own cases, the duration was much longer. The treatment consisted in washing the parts with a solution of potassium permanganate, 1 to 2,000, or with weak solutions of lysol, or in irrigations with silver nitrate solutions varying in strength from 1 to 2,000 to 1 to 500. The child should be placed in the dorsal position with the knees apart. The patient should sleep alone. New-born children, whose mothers had the disease, should have the vagina washed with a solution of silver nitrate.

Dr. H. W. Berg opened the discussion. He said that some time ago, in the scarlet-fever ward of the Willard Parker Hospital, a number of children were found to have vaginitis. The discharge was examined repeatedly, but no gonococci were found, and the conclusion was reached, that it was a scarlatinal vaginitis. However, a little later a number of cases of ophthalmia developed, and the patients were isolated. The absence of the gonococci did not prove anything.

Dr. A. Ernest Gallant said that he thought masturbation was an important factor in causing vaginitis in children, either by infecting themselves or their playmates. He told of a boy, fourteen years old, who had had connection with a woman and had contracted gonorrhœa. He then "played" with a girl of ten years, and she, in turn, with another girl of fourteen years. Children who masturbated would spread the legs widely when put upon the table for examination, and, in female children, there would be enlargement of the clitoris.

Dr. Welt-Kakels, in closing the discussion, advocated thorough examinations of the vulva in children, adding that, if this were done systematically, this disease would not be so often overlooked.

---

**An Experimental Study on the Effect of the Blood Serum of Normal and Immunized Goats in Modifying the Process of Tuberculous Infection.**—Albert George Nicholls concludes that, as a result of his experimentation as well as those of others reported in his paper, we are justified in holding that it is possible to prepare a serum that possesses in a notable degree antitoxic properties against tuberculosis. Whether the various sera prepared are of much clinical value is, to his mind, doubtful. The results claimed even for the Maragliano serum are not so good that we ought to pause in our efforts to obtain a yet more powerful serum. It may be that we have almost reached the limit of potency in the sera prepared by the methods described, and Koch is, perhaps, right when he says that immunity to the toxic products of the tubercle bacillus does not necessarily mean immunity to tuberculosis. We probably need some serum powerful enough to destroy the tubercle bacillus in the tissues, or one which will stimulate the body cells to elaborate a germicidal substance Further advances in this direction will have to be made on the line of Behring's recent work, who has succeeded in producing immunity in calves by injecting them previously with attenuated germs of human origin Possibly by a modification of his methods we may be able to elaborate a serum of the potency required. If not the problem will have to be attacked on quite different lines.—*The Montreal Medical Journal.*

## BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held at Swansea, July 28, 29, 30, and 31, 1903.*

**Special Cable Report to the Medical Record.**

GENERAL SESSIONS.

(Continued from page 193.)

THURSDAY, JULY 30—THIRD DAY.

THE third general session was held in the afternoon of Thursday, as is customary in order not to interfere with the annual dinner of the association which is always set for the evening of the third day of the meeting.

**Address on Surgery.**—Mr. A. W. MAYO ROBSON, F.R.C.S., of Leeds, the orator of the day, took as his subject the reminiscences of a third of a century of surgical work. He began with the year 1870, antedating the Listerian period, and described the state of surgical practice at a time when antisepsis in the operating room was not thought of, even ordinary cleanliness being regarded practically as of secondary importance. The changes consequent upon Lord Lister's epoch-making discovery were great, indeed, and revolutionary in their effect upon the art of surgery.

**Abdominal Surgery.**—The speaker then reviewed the progress which had been made in various directions, in the management of cases of rupture of the bladder, in the diagnosis and treatment of appendicitis, etc. In illustration of how the surgeon of the present day undertook fearlessly and with happy results operations which it would have been little short of foolhardy to perform in the early part of the period under review. Mr. Robson reported a case of panhysterectomy which he had recently performed upon a woman, seventy-two years of age. The operation had been eminently successful in its results, and the elderly patient made an excellent recovery, having suffered but little from shock. Up to within a comparatively very short time the mortality following excision of the gall-bladder was 23 per cent., but there had been no death in the last fifty operations of this nature in the speaker's practice. The results following hepatotomy were also steadily improving. The operation of gastroenterostomy was often successful in relieving the symptoms even when the diagnosis of cancer for which it was performed had been erroneous. Surgery was constantly winning new triumphs in the treatment of diseases of the pancreas and of the intestine as well as in ectopic gestation. Much of the advance in abdominal surgery was due to the wonderful genius of Lawson Tait, who had demonstrated the tolerance of the peritoneum to operative interference under proper conditions of cleanliness. In operations on the kidney also the wonderful progress of modern surgery was most evident. Mr. Robson reported from his own practice 130 kidney operations with 122 recoveries, or nearly 94 per cent. These cases included simple incision into the kidney, the removal of calculi from the renal pelvis, and the fixation of the floating kidney. Abdominal surgery had, indeed, sprung into being during the third of a century under review, and in that brief time had made startling advances, but it had by no means yet reached the limit of its possibilities, and no doubt many more triumphs awaited it.

**Cancer.**—Mr. Robson then referred to the great activity at present displayed in the study of malignant neoplasms. Research regarding the nature and pathogenesis of cancer was being prosecuted throughout the world, and we might reasonably hope that within, at most, another decade the disease would be traced to its source. When this had been done we might confidently look forward to the discovery of some means of cure other than by excision. In the meantime, the pathogeny being unknown, surgical measures were able to grant temporary relief from pain and other distressing symptoms and respite from death, and sometimes they even effected a cure, that is to say, the new growth did not recur after removal by the knife. But medical men were looking forward to better results after the discovery of the cause of cancer, and then it might be possible to prevent or cure the disease by means, perhaps, of an antitoxin or by some other form of serum therapy. When that time came the sufferers would no longer look to the surgeon for an amelioration of their lot, but might turn with confidence of cure to the pathologist and the physician.

**Antistreptococcus Serum.**—The discovery of an antiserum for use in the prevention and treatment of streptococcic infection marked a great advance in surgical practice. Probably all his hearers, the speaker said, were cognizant of cases in which most excellent results had followed the use of this serum, and probably also of other cases in which its employment had failed to benefit the patient. This uncertainty in results might be due to any of several causes. Improvements in the mode of preparation of the serum would doubtless be effected, and further experience in its use, whereby we should be in a position to say with greater precision when and how to employ it, would enable us to calculate on better results, for we should then know what cases were amenable to relief by serum injections and what were unsuitable for this mode of treatment. Already, Mr. Robson said, surgeons were coming to resort more and more to immunizing injections of antistreptrococcus serum before undertaking operations in certain regions, as on the tongue and in other parts of the mouth and throat, in the rectum, etc., where an aseptic field could not be counted upon with any approach to certainty.

A vote of thanks to Mr. Robson for his interesting and scholarly address was moved and unanimously carried, and the session was then adjourned, to meet at the annual dinner in the evening.

FRIDAY, JULY 31—FOURTH DAY.

At the closing session, at which there was but a slight attendance, no business of general interest was transacted, the time being chiefly occupied with votes of thanks to the authorities of Swansea and to others who had extended courtesies to the members of the association, and with formal business. For the afternoon and evening of this day and for Saturday many excursions and receptions in honor of the members were planned. The greater number of those present, however, returned home on Friday.

WORK IN THE SECTIONS.

The following were the subjects announced for discussion in the several sections, reports of which will be forwarded by post:

*Section on Medicine:* (1) The Medical Treatment of Inflammation in the Cæcal Region; (2) Susceptibility and Infection; (3) The Treatment of Gastric Ulcer.

*Section on Surgery:* (1) Practical Experience Regarding the Most Satisfactory Methods of Performing Intra-abdominal Anastomosis; (2) The Treatment of Advanced Tuberculous Disease of the Knee-joint.

*Section on Obstetrics and Gynecology:* (1) The Management of Pregnancy Complicated with Uterine Fibroids; (2) The Diagnosis and Treatment of Tuberculosis of the Uterus and Adnexa.

*Section on Tropical Diseases.* (1) The Disposal of Excreta in the Tropics; (2) Trypanosomiasis; (3) Leprosy, Its Etiology, Histology, and Treatment.

---

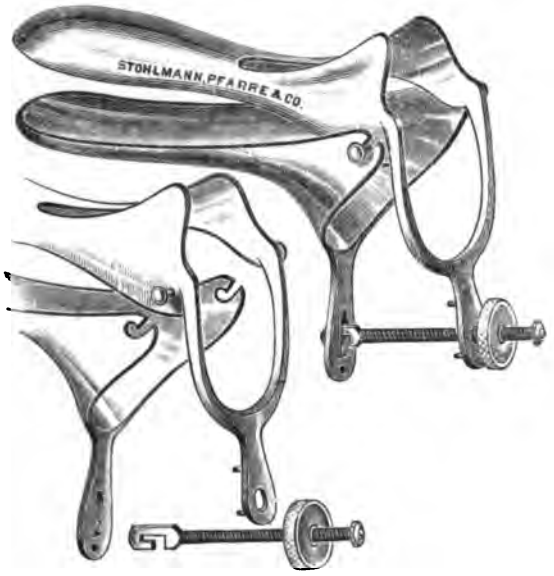
**The Prevention or Amelioration of Vomiting During the Administration of Chloroform.**—E. Stuver has applied a solution of cocaine to the nasal mucosa in about twenty cases of chloroform administration, and the results in quieting gastric irritability have been most satisfactory. He uses a two-per-cent. solution of the drug, and applies it about ten minutes before commencing the anæsthetic. It is a well-known fact that cocaine in the nose inhibits reflex gastric irritation.—*Denver Medical Times.*

# New Instruments.

## MODIFICATIONS OF BREWER'S SPECULUM AND BOLDT'S SCISSORS.

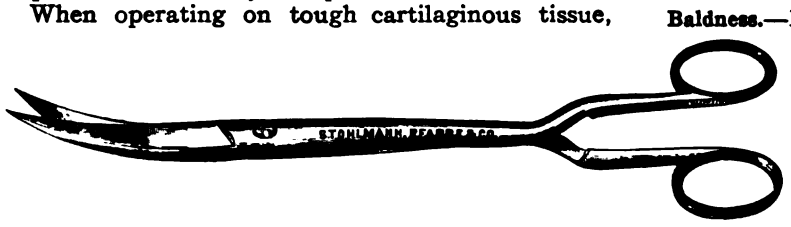
By C. J. KANE, M.D.,
PATERSON, N. J.

One of the chief objections against the complicated vaginal specula of to-day is the difficulty with which the blades are separated for cleansing. Most of them are locked by screws, which gather



dirt and rust and become so tight *in situ*. that their removal is difficult without disfigurement or breakage. The Brewer speculum is the one which is in most general use, as it gives so clear a view, unobscured by any part of the instrument. The objection to it is, as stated above, the difficulty in cleansing. In my modification of the instrument, the shape and size remain the same, but the two binding screws have been removed and two heavy pins and curved slots substituted. The clamp-screw, bar in the old instrument was fastened by a pin in the lower blade, and was therefore locked in place, so that the blades could not be separated from the bar. This has been changed to a screw-bar having a bayonet-lock opening, which hooks on a heavy pin. The clamp-screw is removable from the bar. The complete instrument consists of only four pieces, viz., two blades, clamp-screw, and bar. The parts can be separated instantly, and replaced in a second or two. When in use, the wider the blades are separated the more tightly are they locked. The changes made do not impair its use as a Syms' speculum.

When operating on tough cartilaginous tissue,



as in the uterine cervix, a pair of strong scissors is a necessary prerequisite. The Boldt scissors are much used for this work, but they seem to me to be rather light and weak, and the blades to be too long. Three years ago I had made an instrument of the Boldt type, but with the blades one-half inch shorter, and slightly more curved, with a heavier lock, and with the shank one-quarter inch longer. The scissors are almost as heavy again as the Boldt, and somewhat broader. They are very powerful, and can be used wherever curved scissors are required. They also remain sharp for a long time, even after repeated boilings. The above instruments were made by Stohlmann, Pfarre & Co., New York.

# Therapeutic Hints.

**Calomel.**—C. W. Kellogg (*Occidental Medical Times*) says that calomel primarily stimulates the lymphatic system, and therefore is the best remedy when the organism is overladen with waste and toxic products. It is to be used only at the outset, for its continuance would cause depression and paralysis instead of stimulation.

**Lumbago.**—

| ℞ | Petrolei | ʒi-ʒii |

4 t. d.

—Robinson.

**Baldness.**—Expose parts affected to pure oxygen gas. Case of skin disease recently so treated in London developed a luxuriant growth of hair.

**Urinary Antiseptics.**—Oil of sandalwood, methylene-blue, salicylic acid, salol, balsam of copaiba, camphoric acid, and oil of turpentine, possess antiseptic properties upon the kidney secretions.

**Ivy Poisoning.**—Icthyol, used in a one to three solution will be found to reduce the swelling, lessen the heat and itching, and prevent the spread of ivy poisoning.

—*Clinical Review.*

**Ulcer of Stomach.**—Food should be stopped by mouth and patient nourished rectally. Absolute rest in the recumbent position, and rest to stomach, subgallate of bismuth, ten grains suspended in oil, three times daily, are the indications in gastric ulcer.

—*Clinical Review.*

**Chlorosis and Amenorrhœa.—**

℞ Acidi arsnosi ..... gr. i
Ferri sulphatis exsiccati ..... ʒss
Pulvis piperis nigri ..... ʒi
Pilulæ aloe et myrrhæ ..... ʒi
M. for 40 pills.
S.: One twice a day, after meals.
—FOTHERGILL.

**Chlorosis with Neurasthenia.—**

℞ Tr. ferri chloridi ..... ʒiiss
Hydrarg. chlor. con ..... gr. ii
Liq. arscen. chloridi ..... ʒiiss
Acidi hydrochlorici dil ..... ʒv
Syr. simplicis ..... q. s. od. ʒiv
S.: Teaspoonful in water, three times a day.
—GOODELL.

**Low-tension Lividity.**—A permanent flushed condition of the skin is sometimes met with in persons who have no definite heart lesions These patients suffer from ulceration upon slightest injury. There is passive localized congestion and subcutaneous infiltration.

General tonic treatment and ergot are indicated.
—*The Hospital.*

**Ringworm.—**

℞ Iodine ..... ʒi
Goose oil ..... ʒi
M. S.: Rub into scalp twice daily till irritation is produced. The patch of hair falls off, and the place looks like alopecia. A new growth soon appears. A cure usually takes place in three weeks. No epilation is necessary. —JACKSON.

**Thrombosis of Femoral Vein in Typhoid Fever.**—The part should be elevated and maintained at rest. Apply the following along the course of vessel thrice daily:

℞ Ung. icthyol .....
Adeps lanæ hydros. .....ää ʒii
Ung. belladonæ. ..... ʒss
—ANDERS' "Practice of Medicine."

**Herpes Genitalis.**—Caustics should never be used, as grave ulceration may follow their use. Employ the simplest antiseptic washes and observe cleanliness by immersing the parts in a warm boric-acid solution or bathing with the same twice daily and dusting afterward with the following:

℞ Europhen, .....
Acidi borici .....ää ʒj
M. W. F. ROBINSON.

℞ Zinci sulphatis .....
Potassii sulphidi. .....ää ʒss
Spir. viin rectificati ..... ʒj
Aquæ ..... ʒvij
M. S. Shake and apply frequently.
DUHRING.

**Lichen Pilaris.—**

℞ Sulph precipitat ..... 05.0
Sapo. potassi. .....
Adepis .....ää 15.0
Ponce pulv ..... 16.0
Or,
℞ Lanolinæ .....
Adepis .....
Sapo. potassi. .....ää 50.0
Napthol. ..... 15.0
Cutæ ..... 10.0
—SAALFELD.

**Fetid Breath.—**

℞ Inf. sage ..... 250.0
Glycerin pure .....
Tct. myrrh ..... 30.0
Tct. lavender .....ää 12.0
Lavaraque sul ..... 30.0
M. S. Wash out mouth as required.

**Use of Menthol in Gastritis.—**

℞ Menthol ..... gr. ½ to 2.
Sodii bicarb. ..... gr. 10–15
M. Ft. chart. No. 1. S. To be given one-half hour before meals. —CAMPBELL.

**Dipsomania.—**

℞ Quininæ sulph .....
Zinci oxid ..... gr. 2
Strychninæ sulph ..... gr. 1–40
Acid. arsenosi ..... gr. 1–100
Pulv. capsici ..... gr. ij
M. et. ft. pil. No. j. S. One pill t. i. d.
—MANN.

**To Check the Diarrhœa in Typhoid Fever.—**

℞ Acidi carbolici .....
Ext. opii ..... gr. j
Bismuthi subnit .....ää gr. xviij
M. Ft. pil. No. vj. S. One pill t. i. d.

**Flatulent Dyspepsia.—**

℞ Bismuth salicylat .....
Magnesiæ calcin .....ää parts 2
Pulv. carbonis salicis. ..... parts 3
Ol. anisi ..... part 1
M. S. One teaspoonful half an hour or an hour before each meal.

*If there is gastralgia:*

℞ Syr. menth. pip. ..... parts 250
Acid hydrochlorici. ..... part 1
Cocaine hydrochlorate ..... part 1-10
M. S. A wineglassful before each meal.
—HUCHARD.

**Sweating Feet.—**

℞ Potassii permanganat ..... 0.5
Aquæ gaultheriæ ..... 50.
M. S. Use as wash at night.

**Sepsis,** in erysipilis, parotitis, variola, etc., give fifteen drops of turpentine in milk thrice daily.
—*Medical Summary.*

**Thrush Complicating Dentition.—**

℞ Tinc. moschi ..... gtt. iv
Aquæ calcis. .....
Aquæ lactucarii .....ää ʒij
Syr. simp ..... ʒj
M. S. Two teaspoonfuls every three hours.

**Piles.—**

℞ Acid tannic ..... gr. v
Cocainæ mur ..... gr. ij
Petrolati ..... ʒiij
M. bene et ft. ungt. S. Apply as often as needed.
—LANPHEAR.

**Hæmoptysis.—**

℞ Potassi bromidi ..... ʒ ij
Chloralis ..... ʒj
Syr. acaciæ. ..... ʒiv
Aquæ ..... q. s. ad. ʒij
M. S. Two teaspoonfuls in water at once, and then one teaspoonful every hour until the patient becomes quiet.

Indications.—To be used if heart is rapid, strong, and patient is excited. Ice-bag or coil on chest.

℞ Tinct. aconiti ..... miv
Aquæ ..... fl. ʒj
M. Teaspoonful every hour until pulse becomes quiet and compressible.

Indications.—Used to quiet excited, overacting heart.

**Administration of Oleum Morrhuæ to Children.—**

℞ Ol. morrhuæ ..... ʒij
Ext. malt .....
Syr. calcii hypophos .....ää ʒss
Pulv. acaciæ .....ää ʒij
Aquæ cinnamomi ..... q. s. ad. ʒiv
M. S. One to two teaspoonfuls after each meal.

**Articular Rheumatism'** is largely a streptococcic infection. Chronic rheumatic inflammation is transformed into an acute process by injecting the blood serum of animals immunized to streptococci obtained from the tonsils of rheumatic patients and grown on ascitic bouillon. —MENZER, *Therapie der Gegenwart.*

**Mercurial injection** made with bidistilled mercury such as dentists use in amalgams.

℞ Lanolini ..... gm. 2
Hydrarg. bidestillat ..... gm. 6
Rub together until the mercury is perfectly extinguished.
Liq. abolene ..... gm. 2
M. S. Inject 0.06 gm. (gr. i) every 3 or 4 days.
—M. L. HEIDINGSFELD.

**Opium habit** may be cured by giving after a cathartic and hot bath ten to thirty drops of

℞ Hyoscin hydrobromat ..... gr. i
Spir vini rect ..... ʒi
Aquæ destil ..... ʒiv
and a second dose of ten drops within from thirty minutes to two hours. This, or a smaller dose, may be repeated every half hour till the patient falls asleep.
—F. W. MILES.

**Scarlatina.**—To prevent or cure nephritis, inject 1 c.c. of oil of turpentine into the outer aspect of the thigh and two days later give twenty-five drops by the mouth in capsule or emulsion. In severe instances repeat on opposite thighs on successive days. —Tobeitz.

**Ethyl Chloride and Nitrous Oxide.**—Ethyl chloride compares favorably with nitrous oxide, in that the period of anæsthesia is longer, and that the condition of analgesia is more marked. An insufficient dose of nitrous oxide allows a patient to feel the pain of an operation, although he may be unable to complain; whereas with ethyl chloride a patient apparently is conscious of no pain, though he may struggle and phonate. With an improved mask, and an increased knowledge of the drug and its administration, combined with the portability of the apparatus, etc., I think we have in ethyl chloride an ex- extremely safe and useful anæsthetic.

—Frank H. Rose, *Bristol Medico-Chirurgical Journal*, March, 1902.

**Gastric Hyperacidity.**—Silver, belladonna, or extract of cocoa, two grains before meals, or 10 to 20, or even 30, grains of bismuth subnitrate before eating, proves a great relief. —Wm. Wormley.

**Gastric Ulcer.**—In gastric ulcer (acute or chronic) the patient should drink before meals a tumblerful of ozonized water (made of one ounce of hydrozone and two quarts of water), and after meals he should take at least two teaspoonfuls of glycozone in a wine glass of water. This is the plan of treatment, and it should be persisted in for such a length of time as is necessary to heal the gastric ulcer.

—R. C. Kenner, *St. Louis Medical and Surgical Journal*, May, 1902.

**Cerebral Hemorrhage.**—Wm. Browning (*N. Y. Medical Journal*, February 15, 1902) cautions against the use of stimulants, saline injections, depressant diaphoretics, opiates, digitalis, nitrites, and muscular exertion.

**Apomorphine as an Hypnotic.**—Coleman and Park state that the drug should be given hypodermatically, beginning with gr. ⅛, and to increase slightly in a short time.

---

**The Principles of Rhinological Practice.**—The views of [illegible] Prenchen are summarized in the following propositions:

1. In the normal nose the nostrils should be of equal calibre and should jointly have a sufficient capacity to at all times supply the requirements of easy nasal respiration.
2. In the ideal nose the walls of the septum are practically plane, and are at no time or place touched by the tissues of the outer wall, in either passage, and, furthermore, no points of contact exist elsewhere therein, so as to interfere with either ventilation or drainage, or prevent the normal evaporation of nasal moisture. (3) While in an ideal nose the septum is vertical and nearly plane, a moderate irregularity thereof will not impair the nasal respiratory functions, provided there are no points of contact or abrupt elevations therein, and the lumen at all points is sufficient. (4) Abnormal redness of the nasal mucous membrane is an unfailing sign of irritation, the cause of which is generally of a structural nature, and, therefore, amenable to surgical treatment. (5) The indications for operative interference depend upon both the subjective and objective symptoms. A noticeable inadequacy of either nasal passage, the presence of excessive or retained secretions, or an abnormal redness of the mucous membrane at any point, are all evidences of abnormality in which, if coupled with inconvenience to the patient, merit corrective attention. (6) In the treatment of chronic hypertrophic nasal troubles, the indication is to remove all abnormal or redundant, or pathological tissues, and, as a rule, the chief indication is to cause the detected tissue to so shrink as nearly as possible to the contour of the bony [illegible]

### CONSIDERATION OF MAMMARY CYSTS IN THE DIFFERENTIATION OF BREAST TUMORS.

BY ROBERT ABBE, M.D.,
NEW YORK CITY.

To the lay mind every tumor of the breast is a malignant one. To the physician there are several varieties, the differentiation of which is as important to him as to his patient. There are gross appearances by which one may readily diagnose advanced malignant tumors, but in their incipiency there is so close a resemblance between various kinds that an innocent growth may be readily mistaken for a malignant one.

There are several reasons why I speak of mammary cysts with emphasis:

1. Because they are much more common than is generally thought.

2. Because in every instance in which these cases were referred to me, they were sent by the physician believing the tumor to be a malignant one, and in each instance the patient expected to lose the breast.

3. Because many physicians and surgeons advise removal of the entire breast even when recognizing the nature of the cystic disease, arguing that if left the gland is liable to undergo malignant degeneration.

As regards the relative frequency of cysts and other mammary tumors, I have been impressed by the records of my own private office work. In former years it was my own custom to regard mammary cysts as degenerative and frequently to remove the gland, but during the last eight or ten years I have invariably tested the nature of the tumor by aspiration before allowing myself to make an absolute diagnosis, because of the great similarity in the feel between deep cysts and deep solid tumors on palpation.

In recounting, therefore, my private office notes, disregarding all hospital work, I find that during eight years I have seen forty-one cases of mammary cysts, and fifty-six cases of scirrhous tumors, besides a number of innocent inflammatory adenomas. This should represent not far from the average experience of surgeons in a corresponding number of cases, inasmuch as the patients were referred to me, or came voluntarily without the slightest chance of selection.

On observation based on this series of cases I call attention to two points that have impressed me:

1. The differential diagnosis, which can be said to be easy and absolute.

2. The cure, which can also be said to be easy and absolute.

I have habitually made diagrams of the localization of the cysts and solid tumors of the breast, from which I have made the charts shown on p. 242.

It is of great interest to note from these that while cysts may be localized in any part of the gland, with a slight predominance only in the upper and outer segment, the scirrhous tumors are almost universally distributed between the nipple and the axilla.

In speaking of the hard tumors, I have excluded adenomas and small sarcomata, as well as mammary induration following old abscess change. Relatively in two breasts both the cysts and the scirrhous tumors appear in almost exactly equal number in the right and left, so that one can say that there is no greater probability of causation from injury to the right or left; but incidentally the localization of the scirrhous tumor on the axillary side of the nipple implies a progressive advancing absorption of some infective cause having entrance at the nipple and advancing along the line of main lymphatic currents.

Cysts, on the other hand, are localized in any part of the gland, and being due to the well recognized cause of fibroid thickening of the galactiferous ducts, with stenosis and retention of duct secretion, they are found in the lower as well as the upper segments, the inner as well as the outer. A tumor in the lower half, therefore, has the greater probability of being a cyst.

Of the forty-one cases of mammary cysts, three-fourths were single cysts, and in one-fourth, two or three, or even four were found. Thirty-three out of forty-one patients were between forty and fifty years of age, the others were over thirty-five years, excepting in two instances. This tendency to fibroid changes occurring during the atrophy of the climacteric has been noted by other observers.

The contents of the cysts varied in quantity from one drachm to one ounce, and the fluid drawn was usually opalescent, whitish and turbid, the deposit on standing, showing a considerable amount of granular fat, a few leucocytes and many small and large round mononuclear cells, whose protoplasm has undergone fatty degeneration.

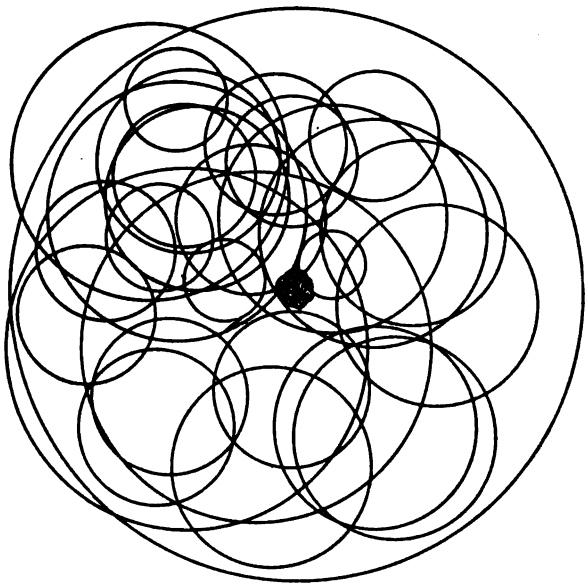
The cyst wall is usually so attenuated as to be imperceptible on palpation when the cyst is emptied. In two instances one or two papillomatous ingrowths were found. In one case, a woman of twenty-one, four such cysts contained more characteristic milk products; the typical galactocele showed activity of the mammary glands; this cannot, however, be regarded in any sense as different from the type appearing in later life, and proved equally curable by aspiration; several years having gone by and the patient is known to have had no return.

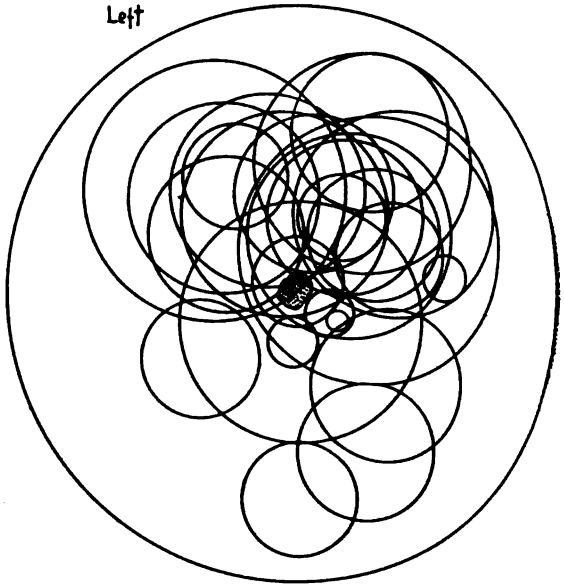
The gross characteristics of these tumors, then, for diagnosis may be said to be a hard tumor of any section of the gland, usually placed rather deeply, never dimpling the skin like a scirrhous one or drawing on the nipple; sometimes quite a flat ovoid; and in the majority of cases not giving a distinct sense of fluctuation on palpation.

It is this deceptive hardness to which I draw special attention because in many cases it is impossible to detect the cystic nature without the use of the aspirator needle; hence the physician should always be ready to pierce every doubtful tumor with a small, sharp aspirating needle, attached to a syringe holding perhaps two drachms, in order to

make his diagnosis certain and to cure the case by complete aspiration if he finds fluid.

There is probably no experience of the surgeon that yields him greater pleasure than to see the profound gratitude of patients who have come to him expecting no less than mammary amputation and to be told when the mammary cyst is aspirated that they are well. That this may be safely said,

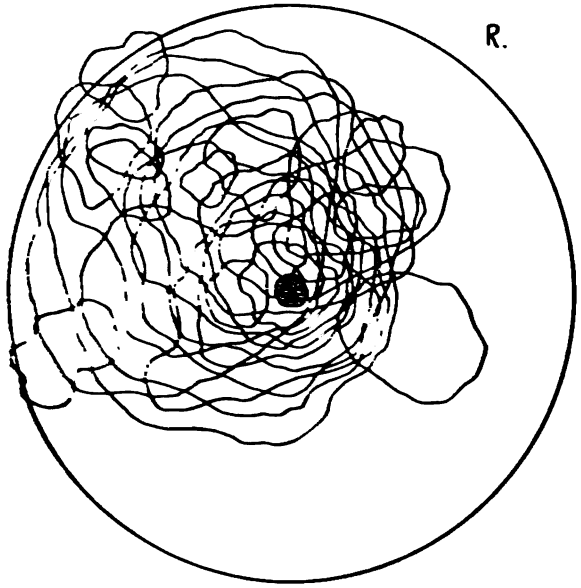


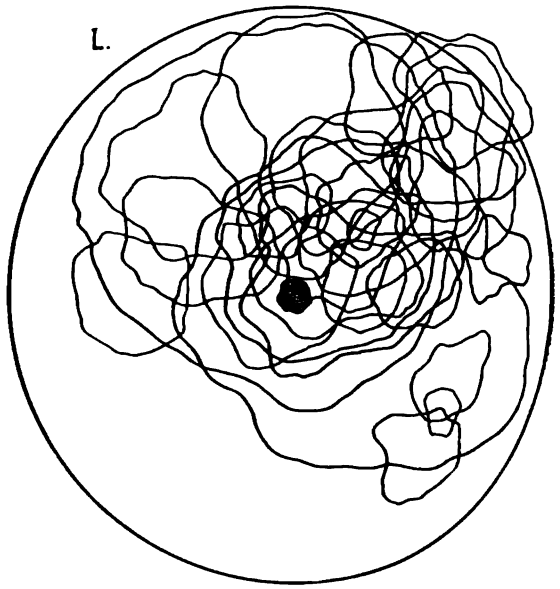


the statistics of the forty-one cases which I have recorded fairly show.

I have corresponded recently with all of these patients, and have knowledge of practically all of them. In only two instances has the cyst refilled, and in these a secondary aspiration cured.

The severe treatment of mammary amputation, at one time widely advised, and still advocated by some, has been much modified in recent discussion,





as the greater innocence of these tumors is recognized.

Quenu has recently advised incision into the cyst with the application of the actual cautery. Others advise injection after the evacuation, carbolic acid and iodine being favorites. Others advise excision of the cyst itself, but not the breast. Paul Segond reports a cure by simple puncture in one case. Thus English and French literature during the past three years is emphatically on the side of severe surgical work in these cases—which I believe to be unjustified.

While one may occasionally encounter a dilated sac or a mammary duct discharging coffee-like fluid from the nipple, or find a cyst which when emptied presents a papillary ingrowth, either of which may require excision of the sac but not of the breast, it stands proved that no case of mammary cyst capable of careful and complete aspiration should ever be subject to any further treatment. It will be cured by that method permanently.

It becomes the duty, then, of every surgeon to test the nature of each doubtful hard tumor by an aspirating needle thrust quickly into its very center, sterilizing the skin by a moment's friction with alcohol.

It is with no little pleasure and satisfaction that surgery presents to the medical practitioner this simple and valuable method with full knowledge that while it will lose to the surgeon many good fees, it saves his fellow practitioner the mortification of mistaken diagnosis (for I have many times returned to the family physician these happy patients), and it gives him a just opportunity to share the glory of applying an exact and finished method to the instant relief of the patient's burdened and distracted mind.

13 West 50th Street.

# PROSTATIC HYPERTROPHY AND ITS RADICAL CURE.

By WILLIAM POST HERRICK,
NEW YORK.

In no branch of surgery has recent progress been so great. From hazardous operations of doubtful efficacy, or palliative measures of still more dubious worth, we are emerging into more uniform methods, and an operation which is serious, but when undertaken at a *proper time*, is giving very definite results. Our responsibility is thus enhanced, and the commonness of the affection, every third man having, when aged, an enlarged prostate, and every eighth one which gives symptoms, lends it an almost personal interest. (Sir H. Thompson.) Moreover, the very wealth of our literature makes it confusing and a review of salient facts of value.

The disease is one of obstruction, and as mechanical and surgical means must be used for its relief, first briefly to recall its surgical anatomy may not be amiss.

1. The prostate is comparable in size and shape to a French chestnut, measuring transversely about one and one-half inches (or 36 mm.) near the base, about one and one-quarter inches (or 30 mm.) in length, about three-quarters of an inch (or 18 mm.) in thickness, and weighs from four and one-half to four and three-quarters drachms (16 to 20 gms.) It is a firm glandular and muscular body. The glandular substance is spongy and yielding, its color reddish gray; it consists of numerous tubular alveoli which unite into a similar number of excretory ducts, emptying into the prostatic urethra. It is associated with a large quantity of plain muscular tissue which forms the principle stroma of the organ. The different portions of the gland are united by areolar tissue and supported by processes of the deep layer of the fibrous capsule and by the muscular stroma. (Quain and Grey.) This normal size, consistency, and structure of the prostate are important in estimating the amount and character of the hypertrophy.

2. "The fibrous capsule, which includes much plain muscular tissue, is divided into two layers, between which the prostatic plexus of veins is inclosed." (Adams.) A true capsule has been described and is often seen as a glistening membrane surrounding the gland in hypertrophy. This is important, as the fibrous capsule also is generally much more distinct and the veins between its layers larger in hypertrophy. In operation it should therefore be respected and the gland shelled out of its fibrous capsule (following the line of cleavage between it and the true capsule), leaving if necessary some of the muscular tissue, as tearing the fibrous capsule gives more hemorrhage and extracapsular dissection is much more difficult.

3. "The prostate is usually described as consisting of three lobes. The lateral lobes form the great mass of the gland and are united with one another in front of the urethra and also behind the urethra below the ejaculatory ducts. The middle lobe, claimed by some to be merely pathological, lies behind the upper portion of the urethra, below the apical portion of the trigone of the bladder and above the common ejaculatory ducts; at the sides it passes without any line of demarcation into the lateral lobes." (Quain.) J. Griffiths finds the middle lobe with its own glandular tissue and ducts distinct in about one in ten cases of the young, an interesting coincidence in proportion to those giving pathological symptoms. "The urethra passes through the prostate from its base to its apex in the median plane about one-quarter of an inch from the anterior surface and nearly one-half inch from the posterior. The two *common ejaculatory ducts* enter at a median depression situated at the upper part of the posterior surface, and passing downward and forward in close contact with one another, open on the posterior wall of the prostatic portion of the urethra." (Quain.)

A regard for the lobular arrangement helps us in estimating the real amount of obstruction present, as there may be severe obstruction with little hypertrophy where we may know that the middle lobe is mainly involved. Also in intracapsular excision it aids in respecting the urethra and some claim the ejaculatory ducts, and in some cases the prostate has been removed without opening the urethra.

4. *The Relations of the Prostate.*—"The base of the prostate is situated immediately below the neck of the bladder, the apex above the superior layer of the triangular ligament. Its posterior surface, which is flat and larger than the anterior, lies against the second part of the rectum, so that it can readily be felt by passing the finger in that organ. The anterior surface is convex and is placed about one-half inch behind the pubic symphysis. (Quain.) Its *base is beneath* and its *apex beyond* the neck of the bladder. To reach it from above, then, we must pass through the summit and base, tearing the prostate up from beneath the neck of the bladder, whose circular fibers largely maintain urinary control, and when torn or greatly stretched generally result in incontinence. We must work at a great depth, where it is often hard to see, with hemorrhage hard to prevent by resecting the capsule, difficult to control, and we leave a raw dead space communicating with the bladder and urine, which is often infected, and drain this up hill unless the patient is subjected to the additional operation of perineal drainage. "On the other hand, the prostate is readily felt from the rectum," one of the greatest aids in diagnosis and showing its accessibility from the perineum. The perineal, then, is the direct route to the prostate.

5. "The prostate is held in position by the posterior ligaments of the bladder, by the fascial continuation of its fibrous capsule and the anterior portion of the levator ani muscle. It has been noted that pressure from a full bladder diminishes the antero-posterior diameter of the prostate and increases the lateral." (Grey.) When in its capsule, then, diffused pressure from the bladder will tend to fix the prostate, and the capsule being opened to depress it and aid in separating it from the capsule while compressing the prostatic sinuses.

6. It is now agreed that the physiological function of the prostate is almost entirely genital, secreting a fluid to mix with the spermatozoa and fluid excreted by the vasa deferentia and seminal vesicles, in the prostatic urethra; in opening the ejaculatory ducts and ejaculating the semen and possibly simultaneously blocking the entrance to the bladder. The former idea that the prostate greatly aided in control of the bladder is given up, as in eunuchs with atrophied prostates, or in children in whom they are not developed, and in women in whom they are absent, urinary control is not interfered with, and now this is borne out, as with many cases of complete prostatectomy incontinence is the rare exception (*e.g.* Syms twenty-three cases, only one partial loss of control of the bladder).

II. A few words concerning the cause and character of prostatic hypertrophy.

(1) The *etiology* has not been demonstrated.

(*a*) Of the *predisposing causes* age is the most important; it is rarely developed before forty-five

or after seventy, generally between sixty and seventy. It is frequent in Europeans, rare in Asiatics or Africans. Conditions causing general sclerosis, as rheumatic, gouty or syphilitic, with over-feeding and lack of exercise, have been cited. We might add that when Griffith's distinct middle lobe was present in children, it would predispose to obstruction later.

(*b*) Of the *exciting causes* most important are chronic inflammations of the deep urethra, as chronic posterior urethritis and prostatitis, which usually precede the vast majority of cases. Frequent sexual excitement without gratification, sexual excess, with the sexual abuses coming under these heads are given, so that the continent and libertine are both liable. All may be summed up in, *avoid chronic congestion of the prostate.*

(*2*) Its *pathology*. Hypertrophy of the prostate is a simple hyperplasia, and may involve chiefly any or all of its constituent elements, glandular, fibrous, or possibly muscular. The epithelial cells are said at first mainly to proliferate, and the gland tissue pressing on the fibrous, from congestion, it also increases. "There are three types: (*a*) diffuse hard scirrhous, (*b*) diffuse adenomatous, and (*c*) encapsulated adenomatous. The obstructions in order of frequency are (*a*) bar, (*b*) middle lobe, and (*c*) lateral lobes." (Keyes).

The pathological conditions caused by hypertrophied prostate have been well divided into: (*a*) Those from obstruction. (*b*) Those from infection. The lateral lobes may enlarge considerably and project only into the rectum, causing no further symptoms.

(*a*) In *obstruction*, however, we have a raising of the trigone, usually near the apex, a pouch forming back of this holding residual urine, and the prostatic urethra passing more sharply upward. If the middle lobe is chiefly involved we may have a bar or more or less ball-and-socket obstruction, if the lateral lobes, some lateral compression, or if the lateral lobes unevenly, a tortuous channel may be formed. With increased expulsive efforts the muscular fibers of the bladder hypertrophy, while later, when unable to compensate, and with distension, an irregular pouching of the bladder. Now, or earlier, the catheter plays its part and is generally the cause of

(*b*) *Infection*, and we have added the lesions of urethritis, orchitis or cystitis, often with a formation of phosphatic calculi in the pouch or pouches of the bladder; the infection traveling upward, those of pyelitis and suppurative nephritis occur, and unless some intercurrent affection has previously carried off the weakened sufferer, exhaustion or sepsis complete the picture.

3. The *symptoms* of these sequent conditions are too well known to us. The *diagnosis* of hypertrophied prostate is, however, of growing importance, as the responsibility of a correct early decision increases with the efficacy of relief. Therefore, when a man past middle age, with a full-sized, but feeble stream, dribbling on completion of urination, complains of frequent micturition, especially at night, and a feeling as though the bladder were not completely emptied, or of retention at times, we must think of prostatic hypertrophy and proceed to *examination*. This is: (*a*) rectal, and (*b*) urethral.

(*a*) *Rectal examination* is conducted as usual except as regards its special object. "The prostate is normally discernible by rectum, but when prominent, is diseased." (Lydston). "The tip of the prostate is felt and we can often pass above the prostate and feel the soft bladder tissue; here bimanual palpation is often serviceable." (White and Martin). Thus we gain a very good idea of the size and conformation of the prostate, whether the enlargement is regular, irregular, or nodular; if it is hard or tender; if pulsation or fluctuation are present; and the condition of the perivesicular tissues. Rarely we combine this examination with a metal catheter, Thompson searcher or sound in the bladder, when the thickness of the tissues between may be noted and a clearer idea gained. About 85 per cent. of obstruction due to prostatic enlargement may be made out by rectum. (Keyes).

(*b*) *Urethral examination.*—The patient having just urinated, lies on his back, the thighs and knees flexed and separated, when, with antiseptic precautions and avoidance of any roughness, we endeavor to pass a No. 18 F. rubber catheter. Failing this, an elbowed, double-elbowed, or olivary-tipped silk-woven catheter may be passed. If neither pass, the examination may be deferred or an attempt made to pass a metal instrument. Note the point on the instrument when the urine first flows, and also when urine stops flowing in withdrawing catheter, if residual urine is present, and the amount of the residual urine. If the metal instrument was used, 4–6 oz. of a mildly antiseptic solution, as one-half strength Thiersch, is introduced into the bladder and the catheter or searcher closed and, being deeply inserted, the tip is turned downward, and we may gain some idea of the depth of the pouch, and drawing it outward as it comes in contact with the posterior border of the prostatic enlargement, note the depth of the insertion of the instrument; then by passing about in several directions, we may gain considerable knowledge as to the shape, size, and character of the obstruction, and may feel a calculus if one is present. Unless there is evidence of stone or other obstruction, soft catheters will not pass and a metal instrument will pass; but this is generally not used. The fluid may be then evacuated and the tonicity of the bladder gauged by the force of the stream through the instrument, and the instrument withdrawn. Now, if the metal instrument has passed easily, without having to be depressed much, and only a small amount of urine obtained, first flowing when the instrument was inserted not over eight inches, there is little or no median prostatic enlargement. Lateral deflections on inserting the instrument show enlargement on the side to which the handle is deflected. As to the depth at which the urine first flowed, allowing about six inches for the anterior urethra and three-quarter inch for the membranous, if the remainder or prostatic urethra is over one and three-quarter inches long, there is median enlargement, and we gain an idea of the length of the prostatic urethra. Special measuring instruments are of little value. The residual urine may have been from 1 to 16 oz.—if of large amount (16 oz.), we should have felt the hypogastric tumor and should remove only a portion at a time, substituting fluid and leaving a proportionate amount in the bladder. The cystoscope cannot be introduced in many of these cases, and generally its information is of little value and sometimes misleading.

The differential diagnosis is:

1. *From genito-urinary inflammations and their results.*—(*a*) Urethral stricture occurs in younger patients, has a small, often forcibly projected stream, is located at less than seven inches depth, and rectal examination shows the prostate not enlarged. (*b*) Seminal vesiculitis and perivesicular inflammation are differentiated by the feeling of the tissues to the rectal touch. (*c*) In acute prostatitis the tenderness, heat and throbbing of fluctuation differentiate. (*d*) Subacute or chronic prostatitis

with deep urethritis are sometimes confusing with a beginning hypertrophy, and it is here that palliative measures achieve brilliant results. (*e*) In cystitis and posterior urethritis the prostate is not enlarged, while vesical spasm, when present, is only temporary, and in contracture of the neck of the bladder the prostate is not enlarged.

2. *Vesical calculus*, which is often associated with prostatic hypertrophy, has more pain, especially on jolting, more frequent and severe hemorrhage, and may be demonstrated by the click of the searcher.

3. *Vesical tumors.*—(*a*) The benign, always rare, especially in the old, are generally sharply localized and mapped out by the finger in the rectum or the instrument in the bladder. (*b*) Malignant, especially carcinoma, are hard and irregularly shaped on rectal examination, with more pain and hemorrhage. Microscopic examination of the urine may show pieces of the tumor and enlarged inguinal glands may be found. The cystoscope may be a real aid here, but unfortunately rapid growth only, may make the diagnosis. (*c*) Cysts lie back of the prostate.

4. *Anatomy and paralysis of the bladder*, by the history of the case, the easy passage of the catheter, the absence of prostatic enlargement and the special tests of the spinal nerves, will be shown. When the diagnosis of prostatic hypertrophy has been established, we should make a complete physical examination, especially in regard to the kidneys, arteries, and general condition of the patient.

III. *The treatment* is best divided into palliative and radical. Palliative, designed to alleviate the patient and delay the course of the disease; radical, for its cure.

Palliative measures here may be operative or non-operative. Radical are alone operative. As in progressive diseases (cancer, for example) radical or curative treatment is often most conservative. We should not here necessarily associate the idea of risk to the patient, with either palliative or radical, as either may be most conservative treatment. Prostatic hypertrophy is not a self-limited disease. Occurring in the old, age may terminate the life before the disease has run its course, but as its termination is fatal, it is best to balance palliative against radical in regard to any case.

(1) To better understand this, we mention some of the palliative measures. These may be classified as Hygienic, Medicinal, Mechanical, and Operative.

(*a*) *Hygienic* has been well summed up in "beware of congestion of the prostate." Avoidance of exposure and wet feet, excesses physical, mental, sexual, or alcoholic. Proper clothing and a diet light and laxative, avoiding meats and rich or fried foods, strawberries, asparagus, grape fruit, and with no beer or champagne, and eating mainly vegetables or cereals, and drinking milk or water.

(*b*) *Medicinal: Internally*, bladder antiseptics as urotropin and alkalies as sod. bicarb., with water to keep the urine below a specific gravity of 1,015, and regulation of the stomach and bowels. The routine use of opiates we but mention to condemn. *Locally:* The appropriate treatment of cystitis, orchitis, prostatitis, and urethritis. As the two latter, with swelling of the porstate and surrounding tissues, may simulate and often precede hypertrophy, it is here that the local treatment, with the withdrawing of any residual urine, achieves much.

Cold rectal douches have also sometimes aided in reducing congestion of the prostate.

(*c*) *Mechanical:* Mainly directed against residual urine and retention by use of the catheter. The aseptic technique for surgeon and patient, the kinds of catheters, etc., the special methods in uninfected, infected, irritable, or obstructive cases are foreign to this paper.

The general rules are well given as follows:

Less than two ounces does not require catheter treatment. Two to four ounces catheterization morning and evening. Larger amounts, three or more catheterizations at regular intervals. Catheterization should be aseptic, gentle, infrequent as above and systematic. (Keyes.) The average catheter life is variously computed at two to six years. We hear of occasional wonderful cases which seem to defy infection—we rarely see them. With wealth and intelligence, supplying the best care, we hear of cases living a dozen years or more, with occasional attacks of cystitis. In the last three years Dr. Syms, in about sixty cases, has operated on twenty-four with one death; many of the remainder, declining operation, are now dead. Let us think of these facts in deciding our course of treatment. Even an infected bladder alone increases the risk of radical cure. The inconvenience to the patient of hygienic and medicinal measures or frequent catheterization, should not weigh heavily, but with a known course of disease, the risks carefully balanced.

(*d*) *Operative:* We class as palliative operations those which do not immediately remove all prostatic obstruction. When trust is placed in subsequent diminished prostatic congestion, or cicatricial contraction, to lessen the obstruction sufficiently, to abolish or mitigate the symptoms, we claim this is a palliative and not a radical procedure, and must essentially have the uncertainty of such. There are three classes of these: (1) Those on the bladder. (2) Indirect operations to affect the nutrition of the prostate. (3) Partial operations on the prostate.

1. Of the bladder operations, we have: (*a*) Aspiration of the bladder: suprapubic, perineal, rectal. (*b*) Cystostomy: suprapubic, puncture incision, perineal incision, prostatic puncture.

*Aspiration:* Suprapubically is alone used, and as an emergency palliative operation dangerous if often repeated.

*Cystostomy* is best perineally, but is only rarely done, generally to improve the patient's condition for radical operation.

2. Indirect operations are: (*a*) Ligation of the internal iliacs, abandoned on account of its great danger and inefficiency. (*b*) Castration, including complete castration, vasectomy, ligation of the vaso deferentia, angioneurectomy, venesection, and injections into the testes.

Their mortality is 8-18 per cent., and in the words of Keyes, "No one has yet brought forward a single proved example of atrophy of the prostate after castration. It may relieve congestion temporarily, but it is not a radical cure." We may add that their great mortality and inefficiency do not recommend them.

3. Partial operations on the prostate: (*a*) Injections of iodine, ergot, etc. (*b*) Puncture: through the urethra by Mercier's prostatome; through the perineum, as by Harrison; electropuncture. (*c*) Perineal section and incision through obstruction. (*d*) Curved transverse perineal section and removal of wedge of middle lobes. (Dittel.) (*e*) Galvano-cautery through urethra: Bottini instrument modified by Friedenberg. (*f*) Galvano-cautery through perineum with or without partial enucleation. (Chetwood.)

All except the last two may be dismissed as abandoned from their uselessness or danger.

*Bottini's operation* has the advantages that with more or less pain it may often be done under cocaine, and is attractive to patients as not being a cutting operation. Almost completely in the dark, it burns

a groove in the prostatic obstruction; if the surgeon burns too much he gets urinary infiltration, and if too little it must be repeated. It leaves a sloughing wound, bathed with urine, in an often infected cavity, with most imperfect drainage, as it is almost always followed by retention of urine requiring a permanent catheter for from three to seven days, and is commonly followed by temperature to 101° or even 104° F. Embolism is not an uncommon cause of death, and secondary obstruction, cicatricial or otherwise, is not infrequent. Its mortality, according to Keyes, is 6½ to 16⅔ per cent., and we may add that it is rapidly losing its adherents. Worse than deep internal urethrotomy, it must share its fate.

*Chetwood's* operation through a perineal cystotomy wound, explores the obstruction with the finger, then incises it with the cautery knife and enucleates portions of the gland with the finger, if it is deemed necessary, and gives perineal drainage. It is then a galvano-cautery, perineal prostatomy and often partial prostatectomy, but it is not truly radical, as in the sixteen cases quoted by Keyes it had to be repeated in two instances, 12½ per cent. In almost one-third of the cases a partial prostatectomy had to be done, and in the eleven cases reported cured, the time of observation is not given, and as in cautery operations secondary obstruction is not infrequent, this is important. Only one case died five weeks after operation—a good showing as regards mortality.

2. *Radical treatment or prostatectomy.*—The term prostatectomy should be reserved, and now largely is, for practical excision of the prostate. The older literature termed a punching out, or removal of a portion of prostatic tissue, prostatectomy. This is confusing, and we should include it under prostotomy.

Prostatectomy may be done by two routes: (*a*) suprapubic; (*b*) perineal.

A brief outline of the main modifications of operative methods may make the matter clearer.

(*a*) In the first suprapubic cystotomy is done and the bladder explored. Early operations merely removed the obstructing mass at the base of the bladder, by cutting, a snare, rongeur or cautery. McGill later, recognizing the great hemorrhage and destruction, cut through the capsule and obstructing mass with serrated scissors from the urethra to the trigone, and enucleated the masses on either side, a fist in the perineum being used to fix and elevate the prostate; afterward an assistant's finger in the rectum was suggested for the same purpose. Belfield later did the same by a finger introduced into the prostatic urethra through a perineal incision. Of this enucleation Keyes graphically states: "The hemorrhage all this while is profuse, so that the operation is performed at the bottom of a pool of blood." And Watson states that the sinuses are larger in the superior than inferior portion of the capsule. Hot saline followed by an irrigation of 1-4000 silver nitrate modifies the oozing, but at times it was necessary to pack the cavity. Post-operative drainage was usually by the double suprapubic tube, at times through the perineum—the large blood-clots forming in the bladder rendering this often difficult and inefficient.

(*b*) *Perineal prostatectomy.*—This severe hemorrhage and the blood-clots, infection of the raw space left by the base of the bladder with imperfect drainage, and the difficulty of the operation, both anatomically and practically, rendering it often incomplete, led Nicoll and Alexander to advocate the pushing down of the gland from above and its enucleation through the perineum, thus sparing the floor of the bladder—the main difference between them being that Nicoll used only suprapubic drainage, while Alexander used both suprapubic and perineal. Later laparotomy instead of suprapubic cystotomy, and pushing down the bladder wall and prostate, was used a few times. (Syms.) Afterward the space of Retzi's was entered and the peritoneum pushed up and the bladder down for the same purpose. This avoided the danger of suprapubic urinary infection and bladder wound, but did not give the bladder exploration, and they were never popular. In some few thin subjects the prostate could be steadied and pushed down without an abdominal wound. About this time, to have reliable pressure from above without an additional operation, Syms devised his retractor, a dilatable bulb on a tube, to be inserted into the bladder through an external urethrotomy, wound dilated with water and the tube clamped; when by moderate traction on the tube, a diffused pressure at the apex of the trigone is obtained, steadying and drawing down the prostate into such reach of the index-finger, that the dissection is done more easily and quickly, making the median urethrotomy wound, the old preferable line of safety, sufficient, and by exerting pressure on the prostatic sinuses, diminished hemorrhage, while the tube, being reflected over the pubes, is out of the way. The diminished hemorrhage we believe to be especially important on account of the age and debility of the patients. The subsequently devised intravesical metal retractors are liable to abrade the bladder mucous membrane and open avenues for infection, do not give the diffused elastic pressure to close the sinuses, need more often to be re-adjusted, and are more liable to be in the way. Hence, we think the rubber one preferable. As confidence and technique have increased, numbers of prostates have been removed by only being steadied and drawn down by a Volsellum forceps or sponge holder, and Murphy of Chicago has devised a pair of retractors to hold aside the capsule and steady the prostate during enucleation, which may be useful. Indeed, some prostates have been dissected from about the urethra without opening it or the bladder, but as perineal drainage is now almost a cardinal principle and the operation must be longer and more difficult, it cannot often be of value. Thus perineal enucleation has been found to be rarely or never as difficult as was supposed. The same reasons which appealed to Nicoll and Alexander are appealing generally, except the necessity of the suprapubic wound, and we now hear comparatively little in literature of the suprapubic and much of the perineal route, which is rapidly being adopted by many of our leading surgeons. (Murphy, Hayden, Squier.) Keyes gives twenty-two cases of suprapubic operation with a mortality of 31.81 per cent. and eight cases of perineal with no death, well illustrating the comparative danger. To subject a weak patient to two coincident operations instead of one, enormously more than doubles his risk, and if it is unnecessary, should certainly be avoided. To illustrate this, Alexander had 25 per cent. mortality in his report of eight cases. Syms twenty-three consecutive successful cases of simple perineal prostatectomy, the twenty-fourth dying. These were average cases, their ages varying from fifty to seventy-eight years. We, therefore, believe in simple perineal prostatectomy in the following manner: With antiseptic precautions, and usually under chloroform anæsthesia, an external urethrotomy is done by dividing the whole length of the membranous urethra on the staff and the incision deepened to the apex of the prostate, which is exposed by blunt dissection. The prostate urethra is dilated with a divulsor. The finger may then be inserted and an exploration made, and should it be

desirable, a cystoscope may be used. The Syms retractor may be now introduced, dilated and traction made. With scissors the fibrous sheath of the prostate is opened and lobe by lobe the prostate is separated from its capsule and removed intact or piece-meal; and thus a large prostate is often removed more easily than a small one, contrary to the ideas of those who, in large prostates, would prefer the suprapubic route. The prostatic urethra is usually opened during this procedure, but rarely suffers any loss of tissue; a large perineal drainage tube is inserted (35) through the prostatic urethra, and the space posteriorly packed with a Mikulicz's tampon, thus preventing largely or entirely the contact of urine with the raw surface; and an external dressing and T-binder are applied. Park uses rubber tissue, somewhat after the method of a catheter en chemise, for a similar purpose. The subsequent care of the patient is practically that of an external urethrotomy. Shock is generally not severe, and if present is treated in the usual manner. The packing of the wound is diminished on the second day, and the wound thereafter treated on general surgical principles. The drainage tube is removed on the fifth day, when the patient is allowed up. During these five days the patient is allowed any position which will not interfere with the bladder drainage. The perineal wound is usually healed in three to five weeks, when the patient is discharged cured, returning at proper intervals for the passage of sounds.

*The causes of death* from prostatectomy have been given as shock, suppression, heart failure, sepsis, embolism and hemorrhage.

*Hemorrhage* is rarely severe when the capsule is opened below, with pressure on the prostatic sinuses and respect of the capsule, where vessels may be caught and ligated, and safe packing controls oozing. In only one case of Syms out of twenty-four was hemorrhage considerable, and then it was comparatively easily controlled.

*Embolism* we believe will be rare when the cautery is given up.

*Sepsis* with a pyramidal wound, its base to the surface, packed separately from the bladder, and contact with the urine, where if necessary, packing is easily changed, will be largely diminished.

*Suppression.*—As earlier cases are operated on and chloroform anæsthesia preferred, will certainly be rarer.

*Shock and heart failure.*—When the technique is merely an external urethrotomy with controlled perineal enucleation of the gland and operation is not the last resort, these should not be an imminent danger. The age and condition of the patient must always be reckoned with however. Patients are often better the day after than the day before the operation, but one patient, seventeen years old, was seen, who died seventeen hours after the operation of heart failure, and considerable shock was present in the case of hemorrhage.

*Of late complications.*—Incontinence is the most important. With no injury to the base of the bladder or stretching of its circular fibers it must be rare. We believe this to be one of the advantages of the perineal operation. Partial loss of control occurred in only one of Syms' cases. Keyes states of radical operation "where atony contraction of renal involvement is not extreme, the result will be perfect," and again "recurrence of the obstruction is, I believe, always due to inadequate operation." Post-operative insanity or cancerous degeneration are possible.

Such are the salient facts of prostatic hypertrophy and its radical cure. It has been impossible in the limits to deal exhaustively with any part, but it is hoped that the sacrifice of completeness may have been gained in clearness.

In conclusion it may be added:

1. That we have not attempted to give the indications for operation. As the statistics of simple perineal prostatectomy accumulate, they will be more definite. Now these cases must be judged more or less individually.

2. When chronic posterior urethritis and prostatis exist, these should receive appropriate treatment, the catheter used to withdraw residual urine, and the result carefully watched.

3. In patients in whom operation has become too hazardous, we must endeavor to improve their general conditon, and, if necessary, do aspiration or perineal cystotomy under cocaine, endeavoring to prepare them for radical operation or alleviate their symptoms. Advanced arteriosclerosis should also be carefully considered.

4. Our responsibility is in recognizing and properly urging operation when indicated; if it is refused we have done our duty, and the patient must abide the issue with such means as remain.

5. Palliative operations should rarely or never be done from their hazardousness and inefficiency.

6. Prostatic hypertrophy is now curable by means of an operation which, though serious, is not hazardous when undertaken in *proper time and manner*. Failure of palliative treatment, of course, gives hope alone through operation, but should be anticipated rather than persisted in. In general infection, especially if repeated, as in irritable cases, obstructive cases unless promptly relieved by its sound and under observation, if residual urine is increasing despite catheterization, or the patient's general health is being impaired, all indicate the time for operation.

7. Anatomically, and now surgically, the simple perineal is the direct and preferable route. Rarely suprapubic exploration or lithotomy may be ad-advantageously added to it.

8. As statistics accumulate, we believe that radical cure may further anticipate the course of the disease.

## BIBLIOGRAPHY.

It is with pleasure that the help of Dr. Parker Syms, verbally, practically, and in his published articles, is acknowledged. Also Dr. E. L. Keyes' "Genito-urinary Diseases," 1903, and Quain and Gray are freely quoted. Among other authorities used we would mention: Morris' "Anatomy," Cunningham's "Anatomy," Deaver's "Surgical Anatomy," McGrath's "Surgical Anatomy and Operative Surgery," Warren's "Surgery," Gould and Pyle's "Surgery," Treves' "Surgery," Dennis' "Surgery," the "Amercian Textbook of Surgery," Kirke's and Foster's "Physiologies," Stengels' "Pathology," Martin's "Pathology," Delafield and Prudden's "Pathology," J. Griffith's "Observations on the Anatomy of the Prostate in the *Journal of Anatomy and Physiology*, Vol. XXIII, 1889;" J. Griffith's "Observations on the Function of the Prostate Gland in Man and the Lower Animals," Vol. XXIV, 1889; Morton's "Genito-urinary Diseases and Syphilis;" White and Martin's "Genito-urinary and Venereal Diseases;" Fuller's "Disorders of the Male Sexual Organs;" Jacobson's "Disorders of the Male Organs of Generation;" Sir H. Thompson's "Diseases of the Prostate;" Watson's "Operative Treatment of the Hypertrophied Prostate." All the indexed monographs in English and some of the foreign articles.

**Sterilization of Water for Troops in the Field.**—In answer to a question asked by Sir Michael Foster in the British House of Commons, in regard to the result of experiments in the British Army as to the sterilization of water for troops in the field, the Secretary of State for War replied that the sterilization of water in standing camps could be arranged, but in the case of moving bodies of troops great difficulty was being experienced in obtaining really satisfactory results.

# THE CAUSATION OF CANCER AND ITS TREATMENT WITHOUT OPERATION.*

By ROBERT BELL, M.D.,
GLASGOW, SCOTLAND.
CONSULTING PHYSICIAN TO THE GLASGOW HOSPITAL FOR WOMEN.

Before we can hope to accomplish anything toward the elucidation of cancer, we must be able to differentiate between the pathogenesis, the pathology, and the premonitory and initial symptoms in each individual form that it assumes. I insist upon this being a necessity before any correct conclusion can be arrived at. No one will, I venture to affirm, deny the fact that, with the exception of scirrhus and encephaloid, each type of the disease differs from its fellow in individuality, source, structural composition, progressive growth, and consequent invasion of the surrounding tissues.

Many theories (not one of which has ever been substantiated) have been adduced to explain the causation of cancer. Among these may be mentioned the eating of tomatoes, the consumption of too much animal food, the preponderance of salt in the dietary, living on a clayey soil, which at times is flooded, and many others; but it would be a waste of time to do more than mention them in a short paper like this. There may be a modicum of truth in such theories, but their importance exists only in the fact that, in certain circumstances, the influence exerted by the various conditions of life mentioned may tend to act prejudicially upon the general health. Thus one is rendered liable to any disease, cancer amongst the number, but the latter only when more important forces are at work.

The occurrence of the various forms of cancer has been attributed by many theorists to parasitic influences; by others it has been viewed as a disease of degeneracy; indeed so many statements have been hazarded on the question, each one pointing to different conclusions, that it becomes quite impossible to reconcile one with the other, and from my point of view, not one of them is reconcilable with the truth.

Were cancer due either to a parasite or a microbe, would we find it unilateral, as it almost invariably is in the first instance; and would it not be invariably accompanied by a rise of temperature, which the presence of parasites, embedded in the tissues, would naturally produce in consequence of the amount of irritation they would excite?

I am convinced that cancer, or rather the elements of cancer, are present in every individual, whether it manifests its presence or not. My reason for making this statement is that I believe the cancer entity is, in its original state, a normal cell, which, from a combination of circumstances, has become altered in character and has assumed a new rôle of existence. It thus loses its benign attributes, and ceases to perform its functions in harmony with its surroundings, becomes aggressive and cannibalistic in its proclivities, prostrating, and then preying upon its neighbors. In doing so, it procreates its species at an alarming rate of rapidity, and by its contact with the neighboring tissues, saps their vitality, and then destroys them when their power of resistance is thus reduced. The physiological condition of these normal cells is displaced by a pathological activity, terrible in its results. Speedily the disease process is conveyed by means of the lymphatics to distant organs, each of which becomes a new center, from which the mischief radiates.

Let us consider certain conditions which, by their combined influences, conspire in an indirect yet tangible manner to cause a temporarily weakened but otherwise healthy tissue to be supplanted by a structure still bearing a strong resemblance to its parent, but which becomes endowed with a power entirely foreign to that which it originally possessed.

The causes of this pathological metamorphosis are apparently trivial in themselves, and therefore liable to be overlooked; yet if they are present in force, they are sufficient to exert a pernicious influence upon the general health, and more especially upon an organ which has had its vital force previously diminished. If an organ has been the seat of prolonged irritation in addition to having had its vital energy reduced, a disease process is most liable to become established.

Let us constantly bear in mind that whatever acts prejudicially on the general health is liable to become a factor in the production of cancer. It is in this way marriage of blood relations, bad ventilation, constipation, excess in eating or drinking, worry, sedentary habits, and the neglect of important hygienic precautions act so perniciously, and react upon an organ, which in more favorable circumstances, would assuredly, by its inherent vitality, be quite able to resist the onset of malignant disease. We must never lose sight of the fact that intrinsically a morbid cell possesses a potentiality very much inferior to that of its healthy and physiologically active neighbor, and it is only when the latter is prostrated by one cause or another that the former is enabled to exert its pernicious potency, which almost invariably becomes progressive. In other words, every circumstance which tends to impoverish or militate against the general health predisposes to cancer. If, therefore, a particular organ is already the seat of a lesion, or if its physiological activity is in abeyance, this organ will become further weakened by injury, and a superadded enfeeblement will thus be conveyed to it. This will render it prone to that kind of cell metamorphosis which results in malignant disease.

It is a most important fact to bear in mind that cancer is essentially a disease of civilization. It is practically unknown among savages, and amongst those who lead a simple, and what I would designate a natural, life. Travelers, who are quite able to recognize it, and who have penetrated the regions hitherto unvisited by the white man, have never recorded a case; there is then no reason to doubt that it is a preventable disease.

To revert for a moment to the statement I made that the elements of cancer are present in every individual, I would like to draw your attention to the palpable fact that ephithelioma invariably retains its epithelial character, proving, I think, conclusively that it derives its origin from an epithelial cell. In scirrhus it is different, for in this case we have a cell or cells which have migrated from a distant organ—most probably the ovary—and have taken up their situation in the mamma, there to assume a new and morbid development if the opportunity arises. But this opportunity must be present before any morbid action is liable to follow. We have a palpable example of what is essentially epithelioma, existing in a harmless, or at least a passive, condition, in a wart. If this excrescence is not interfered with, the probability is, it will remain as a disagreeable disfigurement and nothing more; but if, on the other hand, it is subjected to rough usage, we know by experience very serious consequences may follow, and instead of a passive nodule we may have arising an active epithelioma. Now, in epithelioma of the cervix uteri, there invariably has existed for a lengthened

*A paper read before the Fourteenth International Medical Congress, held in Madrid, April 23-30, 1903.

period, prior to its manifestation as such, an enfeebled condition, not only of the uterus itself, but of the general health of the individual. The latter has been contingent upon, if not in a great measure due, to a prolonged existence of endometritis, with its train of concomitant symptoms of neurasthenia, and consequent prostration of functional activity of all the organs of the body, until the whole gear of the economy is thrown out of healthy working order.

No one will, I presume, gainsay that the integrity of the epithelium depends largely upon the unimpaired integrity of the thyroid body. Not only are the mucous membranes and skin dependent upon this organ, to a large extent, for the continuance of their health, but according to Charcot, Bonilly, Tuffier, Guinan, and others, there is a direct physiological relationship between the thyroid and uterus, which fact was well known to the ancients. If we consider for a few moments what the functions of the thyroid gland are, we cannot, I think, but be convinced of the important part it plays in maintaining the healthy standard of the blood. Dr. F. Blumm maintains that the function of the thyroid gland is to seize upon and render innocuous certain toxic substances, which are constantly produced in the intestine, and absorbed into the blood. It is in this relation, I am convinced, that the administration of thyroid extract produces such a beneficial effect in the treatment of cancer. It must be borne in mind that toxic substances most certainly are continually being absorbed in large quantity when constipation is persistent, and this will be accentuated when there has been over-indulgence in certain articles of diet which contain a large proportion of nitrogenous material. The enterotoxæmia, which results, tells in two ways, first there is a contaminated blood stream, which acts perniciously upon the nervous system, and through it upon every organ of the body. The functions of the thyroid, as a consequence, are prejudicially affected, and its power of neutralizing the toxic material referred to is reduced. This, therefore, accumulates in the blood, giving rise to pathological changes of serious import. In the second place, if saccharomycetes also be present in the blood, which we know is not at all an uncommon incident, they by their power of producing fermentative changes, seize upon this toxic material, transforming it into uric acid, and we have uric-acidæmia resulting. This condition of the blood we know interferes seriously with cell metabolism, and in this I maintain we have one of the principal predisposing causes of cancer. The continuance of the formation of enterotoxins also accounts for the cachexia which is generally coincident.

From the fact that certain animals fed on a milk diet remain in good health after thyroidectomy, but die when a meat diet is substituted, one is naturally led to the conclusion that in cases of cancer, it is advisable to abstain from food containing a large proportion of nitrogenous material, and substitute a dietary containing a preponderance of milk. From the evidence we have to hand, I am led to the conclusion that a diet which is composed largely of flesh meat tends to the production, of definite toxins in the intestinal canal, and it is these toxins of intestinal origin, or enterotoxins, for which the thyroid gland, in a normal condition, seems to have an affinity, and which it seizes upon, fixes, and finally neutralizes. Probably the toxins which arise in the course of a milk diet and a meat diet respectively, differ in quantity rather than quality. The possibility therefore of neutralizing the effects of the enterotoxins by the administration of thyroid extract is of great importance.

We must not, however, rest satisfied by depending solely upon the beneficial effects obtained by the administration of thyroid gland in the treatment of this disease, but simultaneously endeavor to destroy the saccharomycetes, which we know are almost invariably present in cancerous subjects, for if their presence is permitted to continue, their effects upon the enterotoxins will inevitably be perpetuated. Now, we know that the most potent destructive agent upon these bodies, with which we are at at present acquainted are the salicylates. It follows, therefore, that in conjunction with thyroid extract, it is desirable to administer a salicylate in one form or another, and by this means remove what I believe to be the chief factor in the production of uric acid. At the same time, constipation, which permits of the absorption of the enterotoxins, must receive our most serious attention. To put the matter in a nut-shell, our first duty is to ascertain that the bowels are completely evacuated once in twenty-four hours, that the dietary is so modified as to be composed largely of milk food, that thyroid extract is administered in five-grain doses three times a day, that along with this ten to fifteen grains of salicylate of sodium are given three times daily, and that the local affections are treated with a view to remove all sources of irritation. Then if the disease has not advanced too far, I am convinced it will yield to this treatment, which has frequently been the case in my hands.

In conclusion, I would venture to sum up the predisposing causes to cancer as follows:

1. Persistent and prolonged retention of fæces containing an undue proportion of decomposing albuminous material, from which enterotoxins are derived, and by absorption conveyed to the blood.

2. The blood thus contaminated produces a depraved condition of the nervous apparatus, thereby handicapping the functional activity of the various organs, interfering with cell metabolism, and eventually culminating in anæmia in young persons, or cachexia in the elder.

3. If the functions of the thyroid gland are at fault, these toxins, which otherwise would be neutralized remain in a position capable of producing serious mischief.

4. If saccharomycetes are present in the blood, this toxic material is liable to undergo chemical changes, resulting in the formation of uric acid, when uricacidæmia will result.

5. The presence of these toxins in the blood, alone or combined with uric acid, exerts a pernicious influence upon cellular structures, and confers upon them a predisposition to take on a malignant metamorphosis.

6. Prolonged or repeated irritation of a part is liable to rouse into malignant activity cells which otherwise would have remained dormant.

7. The vitiated condition of the blood by prostrating the physiological vitality of the various organs and cellular structures and paralyzing the *vis medicatrix naturæ* affords every facility for the new growth to establish its identity, and increase its area at the expense of its environment.

**Diphtheria Spread in Paris Schools by Pencils.**—According to the Paris correspondent of the *Lancet*, a medical inspector of schools in Paris has discovered that diphtheritic infection among school children is spread by means of pencils. Surely medical inspectors of schools in this country have drawn attention to this means of infection on more than one occasion.

# PATHOLOGY AND TREATMENT OF PNEUMONIA.*

By JOHN NORTH, A.M., M.D., Ph. C., F.S.Sc. (London), TOLEDO, OHIO.

PROFESSOR OF DISEASES OF THE NOSE, THROAT, AND LUNGS, TOLEDO MEDICAL COLLEGE; PRESIDENT OF THE NORTHWESTERN OHIO MEDICAL ASSOCIATION.

If it were only possible to destroy all books and other writings on pathological histology, pathology and treatment of diseases and to obliterate all knowledge of them from our minds, what a great blessing it would be to the modern pathologist and therapeutist. I would also include all past knowledge of physiology and to begin the study of these subjects according to our present knowledge of them. To be able to wipe out all the past theories and pseudo-scientifics, facts with which they are lumbered and only have to master that which is accepted as truth by our profession.

If we examine our best and latest textbooks upon pathology, page after page is taken up with unimportant theories. The entire work is only a revision of some old work written fifty or a hundred years ago. Works on pathology devote most of their space to pathological histology. The true pathology that they contain could be written in a few pages. The term pathology is used instead of the proper term, pathological histology or pathological anatomy.

I know of no disease in which we have such a mass of antiquated ideas still retained, as we have in pneumonia.

By pneumonia, I refer to that disease produced by the pneumococci and not other diseases resembling it, in which we have an inflammatory process going on.

Pneumonia, pneumonitis, lobar pneumonia, croupous pneumonia, lung fever, and other names applied to true pneumonia, are usually defined as inflammation of the lungs.

I will give some of the old and modern definitions of pneumonia:

Wood.—The name of pneumonia is now usually applied to inflammation of the spongy tissue or parenchyma of the lungs.

Page.—Pneumonia or pneumonitis signifies inflammation.

Gould.—Inflammation of the lungs.

Ingals.—Lobar pneumonia consists of an inflammation of the vascular structure of the lungs with accumulation of inflammatory exudation in the air cells, whereby they are filled and rendered impervious to air.

Palton.—Pneumonia is an acute inflammation of the lungs of infectious origin.

Anders.—An acute infectious disease caused by the *Micrococcus lanceolatus*, which produces a specific imflammation of the parenchyma of the lungs and marked constitutional disturbances.

Osler.—An infectious disease characterized by inflammation of the lungs, etc.

When I graduated in medicine in 1868, it seemed to me that there was something about pneumonia that was not explained by considering it an inflammation of the lungs. The clinical history was so contrary to well-defined inflammation. For the past thirty years I have taught that pneumonia was not an inflammation of the lungs, both in lectures and clinics, exactly what it was, I did not know, but I did know that it was not a true inflammation. In 1888 I read a paper before the American Medical Association in which I said that pneumonia was not an inflammation of the lungs, but was a disease produced by some disturbance of the vasomoter system of the double blood supply of the lungs. At that time I had not accepted the germ theory of disease.

I found no explanation of my theory of the pathology of the disease, till after Dr. Andrew H. Smith of New York wrote the article upon Lobar Pneumonia in the sixteenth volume of the "Twentieth Century Practice of Medicine." This article made clear to my mind ideas and theories that I had taught for over thirty years.

Dr. Smith's definition is as follows:

"Lobar Pneumonia is an acute disease in which a specific parasite invades the air cells of one or more pulmonary lobes, where it grows in a fibrinous medium exuded from the functional capillaries, and generates a toxin that infects the system at large. The local process causes consolidation of the affected area by filling the air cells with the effused material, which material is afterward removed, leaving the structure of the lung intact."

In regard to the double blood supply of the lungs, Dr. Smith says: "The lung differs from all other structures in having two separate circulations: the nutritive, supplied from the left side of the heart through the bronchial arteries, and the functional supply from the right side of the heart through the pulmonary artery. This double circulation underlies all the phenomena of pneumonia, and must be recognized in any definition of the disease, as without it the disease itself could not exist."

I believe that our high death rate in pneumonia comes to a great extent from our antiphlogistic treatment of the disease. I do not deny that we may have inflammation of the lungs, but I hold that pneumonia is not an inflammation of the lungs. Again, I quote from Smith: "As to the relation of the specific organism to the disease as a whole, we may note:

"First: That no amount of traumatism inflicted upon the lung, be the methods ever so varied, produce pneumonia. We may cut, pierce, bruise, burn, or scald the lungs; we may introduce mechanical or chemical irritants into the air passages, and while we get inflammation as the result, we do not get pneumonia.

"Second: We may have pneumococcic infection in several serous and synovial cavities at the same time, resulting in suppuration in each, and not have pneumonia.

"Third: We may introduce the pneumococcus into any portion of the body, save the lungs, and even into the blood itself, and we do not get pneumonia.

"Fourth: But if we introduce active pneumococci into the parenchyma of the lung, we always get pneumonia as the result. Pneumococci are always found in the lungs in pneumonia, often in connection with other micrococci."

If we carefully study the pathological histology of a case of pneumonia, we do not find evidences of inflammation in the sense in which it is understood when applied to inflammation as it occurs in other tissue.

In inflammation we have effusion and the passage of leucocytes from the capillaries of the *nutritive circulation* into surrounding tissue. In inflammation of the lungs we would find this infiltration into the parenchyma of the lungs coming from the *nutritive capillaries*. In pneumonia we find the effusion and passage of leucocytes into the air cells: open cavities, and from the capillaries of the *functional blood supply*, altogether differing from inflammation. There is no change in the parenchyma of the lung, and but little effect upon the epithelium

*Read before the Academy of Medicine, Toledo, Ohio, April 1, 1903.

except that caused by pressure of the effused product from without. Inflammation effects the tissue itself, and causes an anatomical change in its elements. In pneumonia this is not the case.

Emmet says that "inflammation causes molecular death," but we do not find this the case in pneumonia. After a few days the air cells are emptied of the mass of exudate with which they were filled, and the cell walls are found practically in their normal condition, having suffered, at the most, only a little loss of epithelium, produced by pressure.

Again the crisis in pneumonia takes place, usually from the fifth to the eighth day, with a sudden fall of temperature and other symptoms, while the physical signs remain the same.

Could this take place if the process was inflammatory?

What is pneumonia, if not an inflammation?

In pneumonia we have a process of germ culture going in the air cells, each cell acting as a culture tube. The pneumococci, finding lodgment in the air cells, irritate the lining membrane of the cell, and then the functional blood vessels throw out material into the cell, which acts as a culture medium in which the germs rapidly multiply. The neutritive system of blood vessels maintain the neutrition of the lung tissue, and prevent its injury. A healthy and a morbid circulation taking place in the same tissue at the same time.

It is a well-known laboratory fact, that any germ acting upon a culture medium, if the medium is limited, after a certain length of time, it cannot furnish material for the production of toxins and nourishment of the germ and it dies. This is exactly what takes place in the air cells. The germ irritates the capillaries of the functional blood supply. Material is thrown out in the air cell, pressing upon these blood vessels and preventing any more exudate. After from five to eight days, the germ has exhausted the supply of culture medium, and ceases to produce any more toxin, which by its absorption caused the chill, fever, and other symptoms. No more toxin being produced, the symptoms subside.

Smith sums up the processes that take place in pneumonia as follows:

"(1) The occurrence of some cause of depression, either local or general, which favors the germination of pneumococci, already present in some of the smaller tubes. (2) The formation of a colony that spreads until it reaches the group of air vesicles that are terminal to the tubes in question. (3) The setting up of an irritation in these vesicles, causing a fibrinous exudation, and emigration of leucocytes, and a diapedesis of red cells from the functional capillaries. (4) The formation of a colony of pneumococci in the medium afforded by this exudate. (5) Arrest of the blood stream in the functional capillaries, followed by accumulation of free pneumic acid in the parenchyma of the affected area. (6) Overflow of exudate into neighboring lobules starting the process in them also. (7) Arrest of germ growth by the exhaustion of the medium and the accumulation of free acid in the tissue of the lung. Up to this time there has been a constant formation and absorption of toxin. (8) Retrogressive changes in the exudate preparatory to its removal by absorption. (9) Probably, in this latter process, formation of an antitoxic principle. (10) Entire removal of the exudate and restoration of the vesicle to its normal condition. (11) Resumption of the functional capillary circulation."

*Treatment.*—If pneumonia is not an inflammation of the lungs it should indicate a radical change in its treatment. A non-inflammatory disease should not be treated the same as an inflammatory one. The patient should be placed in bed in a large, well-lighted, and well-ventilated room. The temperature should be kept at about 65°. Above all things, a patient with pneumonia should not be removed from a warm bed and a warm room and placed in an ambulance and taken to a hospital. I would much rather attempt to treat a patient with pneumonia in poor hygienic surroundings than take the risk of removal to the best conducted hospital. A case of pneumonia is certainly not benefited by removing it from a warm bed to a cold ambulance, and then the exposure incident to a long ride does not add to his chance of recovery. The risk of removing such cases is attended with great danger. The importance of placing a patient with pneumonia in bed and keeping him there should never be overlooked.

F. K., a strong, vigorous young man, called at my office one morning. He had some premonitory symptoms of pneumonia; in the afternoon he had a chill with evidences of consolidation. I sent him home and placed him on treatment with instruction to go to bed. I visited him twice the next day. He was progressing well. I instructed him not to get out of bed under any circumstance whatsoever. The next morning, the third day of the disease, I visited him and found him in rather a nervous condition, symptoms not so favorable as the night before. He said that he awoke about four o'clock and felt so well that he got up and went to the watercloset, and run all over the house, went into his parents room and sat on the bed, and talked for some time, till he felt chilly, then went back to bed. The house was cold and damp. I told him I did not like his condition and was afraid that he would be worse, having disobeyed my directions. He said he was all right and wanted to get up and dress. I instructed him to remain in bed. At eleven o'clock I was sent for and found he had been having a chill, high temperature, full bounding pulse, flushed face, great dyspnœa, and in a high state of nervous excitement. I considered him in a very critical condition, and called Dr. Collamore in consultation. We bled him freely, which afforded temporary relief of the dyspnœa, but it soon returned again. He continued to get worse and died a short time after midnight, the beginning of the fourth day of his sickness. One of us was with him until death took place. If he had followed instructions and remained in bed and kept warm, I have no doubt he would have recovered, as he was doing well up to that time.

The food should be light but nutritious. Milk is the best diet.

No medicine should be given in any disease unless we know just what we expect it to do. Do not give any remedy for pneumonia just because it has been recommended in the disease. Some remedies may be good for pneumonia, but very bad for men, women, and children afflicted with the disease, and then, during the course of the disease, the local and constitutional conditions are undergoing a change. The remedy indicated to-day might be of injury to the patient to-morrow. Mix your remedies with brains.

The surgeon of to-day uses but few medicines, but he studies those few well and knows just what he can do with them. He has the latest and best instruments and appliances, and he knows just how to use them to get the best results.

How is it with the physician of to-day? He has his laboratory, his microscope, his hematometer, his reagents, and other instruments of precision. He

can make out a beautiful diagnosis, but then he is at a loss to know what to do. The physician of to-day does not know as much about therapeutics and the action and the limit to remedies as did his predecessors of twenty-five to fifty years ago. When he has made out his diagnosis, he takes up a price list of tablets and proprietary medicines and runs down the list till he comes to the name of the disease he has diagnosed, and gives it to his patient. Nearly 50 per cent. of all prescriptions are for patent or proprietary medicines.

Physicians are becoming diagnosticians instead of therapeutists.

If I see my patient during the prodrome before the chill I place him in bed and give him a brisk mercurial purge, followed by a siline. By this I empty out the alimentary canal and stimulate secretions. Full doses of quinine at this stage may abort the disease and prevent the chill. As we seldom see the patient until after the chill, we have to resort to other means. If I see the case within a short time after the chill, I give one grain of opium, also giving a few small doses of calomel followed by a saline. Tincture of aconite, in drop doses, should be given every hour. After engorgement and exudation has taken place, I place the patient on quinine, two grains. Ammonium chloride, three to five grains. Tincture aconite, one to two drops, and svapnia one-tenth grain, made into capsule and given every two hours, from the time of the chill until the crisis takes place, giving it day and night, arousing the patient from sleep if necessary. There is no stage of the disease, prior to the crisis, contraindicating the use of all these remedies. Other remedies are used as indicated.

Quinine is one of the best remedies I have used in pneumonia. In the beginning, full doses will sometimes abort the disease. As indicated, I afterward give it in two-grain doses every two hours, twenty-four grains every twenty-four hours.

Dr. A. A. Palmer read a paper before the American Medical Association on "The effects of Quinine in the Treatment of Acute Pneumonia," in which he demonstrated the use of this drug as a therapeutic agent. He says, "I cannot doubt that quinine is capable, when properly used, certainly in the early stages of the disease, of arresting its progress in a large majority of cases, not only mitigating the fever, but preventing the full development of the local inflammation. Quinine does not only reduce the fever, but it has a special tendency to relieve internal congestives; it brings the blood more freely to the surface, and induces perspiration, and if we can rely on modern experimental observations, it diminishes the production and the amœboid movements of leucocytes, and thus diminishes exudation."

In pneumonia the leucocytes increase from 9,000 in health to 10,000 or 12,000 in mild cases, to 30,000 or 50,000 in severe cases per cubic millimeter of blood. Quinine prevents the rapid production of leucocytes. It also prevents their amœboid movements, and retards their passage out of the vessels into the air cells.

To show this action of quinine, I have often, in class work, taken the web of a frog's foot, placed it under the microscope and observed the movements of the white and red blood-corpuscles intimately mixed with each other in the center of the current. Now apply a slight irritant to the field and we will see leucocytes leave the central current and flow along the wall of the vessel, adhering to the surface. Some of them become lodged, elongate, break loose, and pass through the coats of the vessels. If we inject quinine into the frog and continue to watch the blood current, we will see the leucocytes assuming their natural shape again, they do not adhere to the walls of the blood vessels, but flow in the current.

In pneumonia we find an increase of fibrin in the blood, the limpidity of the blood with its alkalinity is diminished. The presence of ammonium chloride in the blood increases its alkalinity, diminishes its viscosity, and prevents coagulation. In this disease, we find the chloride of sodium in the urine very much diminished or absent. The accumulated material filling up the air cells, contain a large amount of chloride of sodium. When ammonium chloride has been administered, it is effused into the air cells, thinning and liquifying the contents of the cell. The sodium chloride is taken up by the blood and eliminated by the kidney. I have proven this action in a number of cases, by analysis of the urine and sputum. Ammonium carbonate will not take the place of the chloride of ammonium. The acidulous radical of the carbonate ($CO_3$) being too easily decomposed and diffusible, will not remain in contact with the compound radical ($NH_4$). Carbonate of ammonium acts as a diffusible stimulant, easily undergoing chemical decomposition and both radicals are broken up.

Aconite is very strongly condemned by many in the treatment of pneumonia. If used in large doses, it should be condemned, but if used in small doses, it is very efficacious and of great value. It relieves the patient and prevents various complications. Tincture of aconite, in one-drop doses every hour, reduces the frequency, force, and tension of the pulse, flushes and moistens the skin, and increases the amount of urine with a corresponding increase of solids. After these are accomplished, aconite should be discontinued.

Bartholow says: "It is more especially serviceable before exudations have taken place, but is not without utility at any stage"

Fathergill says: "Aconite dilates the arterioles and greatly increases the capacity of the vascular system, and in this way drains blood away from the engorged part; in fact, this drug 'bleeds the patient into his own vessels." Norwood's tincture of veratrum viride, if given in large doses at the onset of the disease. will accomplish this better than aconite.

Opium, or its derivatives, is another remedy that I use throughout the disease. If the case is seen early, a full dose of opium, one grain, is given; after this, opium should be used in small doses. I prefer svapnia to other forms, given in one-tenth-grain doses every two hours. In such doses it acts as a stimulant to the respiratory centers, does not arrest secretion, but acts as an expectorant, relieves the cough and makes expectoration easier. Large doses of opiates should never be given, except in the beginning of the case. Since the introduction of heroin, we have a remedy that is very efficient in the treatment of pneumonia. One-twelfth of a grain, in tablet form, will quiet the nervous system, produce sleep, lower the temperature and pulse rate, diminish and increase the force of respiration, and make the expectoration much easier.

Alcohol, strychnine, nitroglycerin, digitalis, veratrum, salicylates, creosote derivatives, saline injections, etc., are all usetul in pneumonia, if used in the proper stage, or to combat complications as they arise. Time will not allow me to take up each one. Warm applications, cold packs, or cold spongings are called for in almost every case, depending upon conditions and circumstances.

517 Madison Street.

# THE PRINCIPLE OF LIFE AND COGNATE THINGS.

By JOS. CLEMENTS, M.D.,
KANSAS CITY, MO.
MEMBER OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Prof. H. D. Halliburton, in his address before the British Association for the Advancement of Science, discussed what he termed the "Revival of the vitalistic conception in physiological work." The statement is somewhat equivocal, is possible and probable of misinterpretation, leaving an incorrect impression of the facts in the case. It is as though the vitalistic conception, holding sway once but since abandoned, is again taken up or "revived," which does not state the case correctly. The vitalistic conception has always been entertained in various degrees of modification. Now, opinion has leaned toward or emphasized one phase of the conception, then a somewhat modified view has obtained, each being but an interpretation of the one constant conception of a force not merely or entirely physical. Life phenomena have never been conceived and interpreted on a purely physical basis, and the conception of "vitality," or a force and principle other than physical, has always entered into the hypothesis of the interpretation. It is therefore not the revival of the vitalistic conception so much as a more general interest in, and a more purely vital idea of the force operative in, physiologic work, which obtains.

Professor Halliburton admits, "It may be that there is a special force in living things that distinguishes them from the inorganic world," etc., and it is the part of science to demonstrate, or disprove, the entity of such special force; but to say that, "Because there is something in physiologic processes that we cannot understand, is no reason for calling it vitality" (Halliburton), does not by any means commend itself as a scientific position to assume.

Is there a something we do not understand? May it be demonstrated as a special force to these phenomena? Can such notion be disproved by accounting for organic processes on chemical and physical grounds? These are questions to be answered and settled if possible, and to solve the problems which these involve is the dignified attitude which medical science assumes.

A consensus of medical opinion will indorse the statement that "the vitalistic conception" of the present day is the admission that there is something in living matter that is not identified with any known physical and chemical activities.*

Is this "may be . . . special force," this "something not identified with any known physical and chemical activities," a chimera, or may its entity be demonstrated? Surely scientific ground for one position or the other may be established!

At least quasi confession of the reality of this "special force" is given by the most ardent objectors to the vitality conception, in the attempt to evidence the "identity of electricity and life."

The time has certainly come when there should be a dignified, scientific essay to settle this first and preliminary part of the "Great Biological Problem:" Is there a special force in organic phenomena? Is it sovereign, dominant in all the processes of the organic phenomena? Is it alone the magisterial, operative principle, or may it be supplemented and complemented by forces external to itself? These are problems not yet fully solved, it would seem, in medical science, the medical mind is much 'at sea" respecting them, hence the charge, in high places too, of "Chaos in Medicine.'

How can there be a correct understanding and interpretation of pathological, or a rational interpretation of therapeutic processes with these questions unanswered, and these problems unsolved?

A pathology based upon the hypothesis of a community of forces operating in organic processes would be wide of the mark were the correct interpretation of the facts in organic phenomena to evidence the entity of a special force, together with its sovereignty and unity in dominance of the processes. This is the position we assume, and the non-recognition of these facts leaves us as unsettled as to the basic principles upon which our pathology and therapeutics are founded as were astronomers, in solar science, prior to the Copernican epoch, nor can it be otherwise while the problems we have before us are uncertain and unsolved.

There will be some approach to a solvement of the problem of life in the endeavor to establish the entity or to evidence the fallacy of a special force in living things.

In the study and investigation of organic phenomena *motion* is what is first seen and conceived. With the best aids to vision a microscopical substance, mostly water, is seen, and which is always identified, and identifiable, as the physical basis of life, of organic phenomena, of every class and grade.

Organic processes are specific, identical, and unique to this one substance, the basis of them. Viewing this substance in normal environment, its first spectacular is motion in increase of mass or size. And this motion is specifically centrifugal, *from* center (Beale), and automatic. The cosmic forces common and operative in inorganic phenomena are not in evidence here, but are held in abeyance, the centripetal motion, in all other save this one instance, being centrifugal. So that the increase in the mass of matter is by force originating in itself, and operating from the center outward.

The original matter, the germ, is the seat and source of this ultimate or initial organic phenomena, metabolism, in association with and of the nutrient substance taken up by and into the bioplasm of the germ. This is followed by the appearance of the so-called "cell," discovering a membrane or cell-wall. The processes continue, increased cellular mass results in disturbed equilibrium with fission and multiplication of cells.

The phenomena are progressive, becoming more and more complex as they proceed, but the initial, or metabolic, process is identical throughout, and in every grade and species of organism, in plant and animal world.

Intake of nutrient substance to be sure; absorption of environmental nutriment, and metabolic process from within outward—centrifugal.

In all this the phenomena are the converse of those cognate to these in the inorganic world, the forces operative in organic processes not being in evidence in organic phenomena in their primordialism, but a force, specific to this basic substance, bioplasm, localized with it, and specifically dominating all the processes germane to the organism, is sovereign.

This distinction in the nature of the processes obtaining in the organic and inorganic domain is marked, and being vital in this discussion needs further illustration.

*The *Journal of the American Medical Association*, November 8, 1902. Editorial: "The Principle of Life."

In the inorganic world in its primordial and intricate phenomena nothing is spectactular. Atoms and molecules, to say nothing of the corpuscular hypothesis, a thousand "corpuscles" to form an atom of hydrogen, are occult to vision, even with the highest modern aids to sight.

In the atomic formation of molecules and their various arrangement motion, of course, enters into the mental process of ideal conception, the motion being centripetal, and by forces in no sense local or especial to the substances operated upon—at least, not so in any such sense as in organic phenomena. True, the universe is an organism in the accommodated sense used by the President of the American Association for the Advancement of Science, in his recent address before that body at Washington.

The great cosmic bodies, and in their entirety, are related, and the laws and forces operating are, in general, the same, universally, but in such sense as to allow the most complete distinction to obtain in the inorganic and organic spheres as to the modes of their phenomena and the principle of their operations.

The organic world, from the spectacular point of view, may be quite inconsiderable, for who can demonstrate, other than as a reasonable speculation, that there is life on any planet save our own? Yet from the nature of its physical make-up, and especially the character of the phenomena obtaining, it bears fine comparison with the cosmos of which it is so minute a part.

It is in the nature of the phenomena obtaining that our world finds its distinguishing characteristic.

Lord Kelvin, recognizing the wide dissonance of the inorganic from the organic processes, says that, "all motion in pure dynamics is reversible," yet maintains that this principle "has no place in the world of life."

Organic phenomena are evolution processes, developmental, progressive.

The microscopical protoplasm manifests motion as the initial expression of the special force of which it is the depository, the action originating within. The living matter comes close to, takes up into itself the nutrient matter of its environment, and, by a unique process, passes on its life and powers to the erstwhile dead nutrient substance, which at once assumes and occupies the position of the parent bioplasm. This, in turn, assumes a changed position, taking on structural form, being now classifiable among the tissues of the organism that is, or is to be, part of it becoming effete, which in the general processes is removed as waste.

This life property is not exerted indiscriminately, but only upon certain selected material found in its nutrient environment. The bioplasm of plants takes up certain inorganic elements and matter, and by a property peculiar to itself, and processes peculiar to plant organisms, brings them into the organic condition. Animal protoplasm has not this property and power, although in what the property consists is not as yet ascertainable, the two kinds of protoplasm being indistinguishable. Animal life would be impossible without the vegetable kingdom.

Here, then, is exerted the life principle, which seems to be an endowment of the living matter alike of the plant and animal, for in the absence of this special substance neither class of phenomena are producible.

If action giving rise to the structural unit of the organism, with the changes and multiplication of it, had not been *seen* the conception of life phenomena, embracing embryology and all physiology, could not have been formed. Motion, therefore, self-action, action automatic and self-originating, is the property of living matter, and, it would seem, of it alone. Other matter is moved by force external to itself and common to other matter and movement, motion in and by force inherent to itself being characteristic of this protoplasmic substance alone. Self-movement, unique in its nature and kind, is a property of protoplasm and special to it and its phenomena, the principle of life being its originating and active force. All motion organic in nature, all the activities of an organism originate in the living matter, the bioplasm of the cell or structural unit. Organic function, tissue motion, as expressed especially in osmosis, and all recognizable activity in an organism originate in and by force of the protoplasmic nucleus of the cells. Physical and chemical activity are secondary and subservient to this, as is evidenced by the fact that the latter are incompetent to the life phenomena without the former.

The question, vital at this hour, is, Are these the facts in the case? Have we stated them correctly? The misconception and misinterpretation of the facts in physiology and pathology, rendering oblivious and inoperable the fact and principle of the sovereignty and unity of the vital forces, or the life principle, in organic phenomena, has given rise to the error of active agency in disease of other than the vital forces, and the equally erroneous notion of active principle in drugs, in the sense of "curative properties" possessed, and therapeutic activities originated by them. What we have elsewhere termed as the huge delusion of a bottled and marketed pharmaceutical "cure" for disease, disastrous alike to the interests and health of the people at large, is the legitimate progeny of the misconception and misinterpretation we deplore. For every disease there is a "remedy" in some drug, is the half-truth which is infinitely worse than the lie, and, were there but money in it, some enterprising commercial pharmacist, assisted by a renegade M. D., would put up in one package the "germ" of a certain disease, and in another the "cure," and so by striking the correct balance befriend the world and gain the coveted revenue, nor is the day so far distant when these strictures will not appear so funny or untimely as possibly they may now.

External things, such as microorganisms, which may very properly be termed disease organisms, do certainly have relation to pathological conditions and processes, causal and adjuvant in rôle, just as drugs do in therapeutic processes leading to restoration to health, but the distinction between cause and origin in disease is a distinction most real and vital. The causal and adjuvant interpretation of the rôle of external things in pathological phenomena recognizes the force special in living things, affording a rational view and interpretation of the processes. This leaves the principle of life in charge, so to speak, magisterial, dominant in the activities, as it certainly is.

The other view and interpretation, making external things—microorganisms, for instance—the active agency in disease processes, involves us in chaos. The hypothesis, acted upon rather than defined and authoritatively taught, that force, other than the special or life force, operates effectively to carry on organic phenomena, while nowhere taught, as affirmed, is nevertheless assumed as the practical basis of pathologic con-

ception and therapeutic interference and exhibition. Is the error not colossal in proportions and disastrous in results?

The test of a theory is in its practical application, hence the question, how does it work? The test here is applicable.

A consensus of medical opinion will certainly support the editorial statement already referred to, indorsing the "something in living matter not identified with any known physical and chemical activities." This "something" is a force which operates organic phenomena, and is special to them, a like principle being undiscoverable as operating any other phenomenon.

True, forces operating in the inorganic realm are seen to be active in organic processes, and are vitally associated with them, but their operations in this special and classic kind are never in the absence of the life principle, and the results of their activities are so different from those that are disassociated with it as to evidence its dominance and control. Chemistry has two branches, inorganic and organic, and the latter evidences the magisterial influence and control of that something not identified or identifiable with inorganic chemistry. In another paper we have shown that the cognomen chemical physiology is unscientific. The fact of the life principle as sovereign in organic phenomena is but partially and tardily recognized, and is not given the dominant rôle which is its right. Other factors and forces are supposed, somehow, to *operate* in organic processes.

A rational view and interpretation of life phenomena, on current hypothesis, cannot be presented to a scientific mind, such as may be done in astronomy and other sciences. Medicine presents an aspect to an independent critic to-day not flattering to its status as an exact science. It hangs less together as to its segments, presenting less of orderly relation and sequence, giving place to empyricism in a disturbing degree, than its real nature and status should allow. As a natural outcome of this we have the "germ theory" of disease, which is utterly without foundation as popularly conceived and interpreted. Wild and well-nigh senseless speculations are indulged hypothecating diseases of "germ" or microorganic origin.

An equally groundless hypothesis and fallacious notion, and which is taught as a theory, is that of active principles in drugs, which in some way originate, not merely in the causal but in the operative sense, the processes therapeutic. A single scientific reason cannot be brought forward in substantiation of a disease of germ or microorganic origin, or of a *drug* containing an active principle. The instrument is in the wrong region of the medical heavens when observation leading to such conclusions are made.

The inconsistencies and crudities inseparable from such groundless hypotheses lead to the confession that "medicine is full of misnomers from which it will never be possible to depart," which without doubt is true enough on the hypothesis of organic processes operated partly by its own special force, and partly by other forces and factors external to itself, but by no means so on the scientific principle of the special force, sovereign and alone in active dominance in organic physiology. On this as the basis of interpretation in physiology and pathology misnomer is, in the main, avoidable and inexcusable.

Why should not the entity of the life principle be fully recognized and its rôle scientifically interpreted?

The phenomena of which physiology is the description, are a series of classic processes having a special force as their principle of operation. In the processes organic, besides the tissues and organs, the vehicles and channels and the forces generated by their activities, much of which may be classed as chemical, there is the special force originating the phenomena in its primiordialism, and in evident and constant dominance throughout the organism and its entire career. Never does its superintending hand disappear or its power cease to be the originating and sovereign force, and when conditions and environment become such that it can no longer be dominant, it disappears, and the phenomena ceases eternally. Chemical processes obtain in a cadaver but no organic chemistry, its originating, sovereign principle is absent. Turn on the batteries, prepare and immerse the body in solutions containing electric charges, and there may be ghastly amusement in it, but the presiding force is gone beyond recall, and the specific phenomenon, organic, is eternally closed.

The phenomena physiologic are orderly, methodic, graded, progressive, and purposive—in a word, unique to the organism, and with the central, sovereign life principle in control.

Crystal formation, as we have discussed elsewhere, is the nearest approach to organic phenomena of which we have knowledge, yet its processes are utterly unlike and the converse of organic motion. In the making of crystals the same general mechanism of building obtains as everywhere in all inorganic things, nor is there the remotest suggestion of anything analogous to the principle of life or the phenomena of which it is the sovereign and sole force, ever present, ever active. The Principle of Life fully recognized, and its rôle scientifically interpreted, would reconstruct pathology and therapeutics in particulars needed, and medical science would emerge, as other sciences have, from the chaos of past conditions, and take its rightful place at once in the front rank, as high as the highest, exact as the most exact, and the noblest of them all.

---

**Sialogogues; Their Therapeutic Employment.**—W. G. Aitchison Robertson says that in conditions of amylaceous dyspepsia great benefit can be obtained by the slow mastication of starchy food. In more aggravated cases the patient should be told to chew slowly some one of the vegetable agents which exert a distinct sialocinetic influence. In cases of hyperchlorhydria, our aim ought to be to secure the digestion of the amylaceous constituent of the meal before the free acidity has had time to check proteolysis. This we can do by increasing the flow of normal saliva. In many cases of feeble gastric digestion the fault is due to merely a diminished activity in the gastric juice, both hydrochloric acid and pepsin being present in less than their normal amounts. When saliva is introduced into such a stomach it has the effect of stimulating a more copious and also a stronger secretion, and so the more saliva introduced, the larger is the amount of gastric fluid which is secreted. In many such cases as he has described, the author has found that a stimulation of the salivary secretion by means of palatable and pleasant vegetable sialogogues, as, for example, ginger, gentian, peppercorns, cusparia, etc., has been of the greatest benefit to the patient. Such bitter agents as cusparia, calumba, gentian, chamomile, etc., exert also a very beneficial effect on the gastric mucous membrane. Other salivary stimulants are at the same time carminatives, as pimenta, ginger, pepper, etc. We can thus obtain both actions from the same drug and employ them therapeutically.—*The Scottish Medical and Surgical Journal.*

## AN UNUSUAL CASE OF EMPYÆMA OF THE ANTRUM OF HIGHMORE.*

By SIDNEY YANKAUER, M.D.,
NEW YORK.

The interest in the following case lies in the unusual attempt on the part of nature to effect a spontaneous cure.

The patient, male, aged forty-eight years, was seen by myself for the first time six weeks ago. He had complained for about two years of obstruction in both nasal passages, intermittent on the right side, but continuous and complete on the left; a discharge in the nasopharynx most profuse in the morning, with the hawking and spitting characteristic of nasopharyngeal catarrh; there were no pain, headache, or local symptoms. He had consulted several specialists, who told him that he had a simple nasopharyngitis, and who prescribed sprays. His condition remaining the same after conscientiously following their directions, his family physician referred him to me on March 19, 1903.

Examination: Both lower turbinates were so markedly swollen that they came in contact with the septum and rendered any view of the deeper parts impossible. After cocainization, a large growth was seen on the left side, under the middle turbinate, about 2½ cm. long, extending downward over the lower turbinate, completely obstructing the posterior half of the middle and lower meatus. It had the shape of a polyp, but instead of having a grayish color it was covered with smooth and congested mucous membrane, with large dilated veins running through. Pus was seen on the floor of the nose. A probe passed readily between the growth and the middle turbinate, but between the growth and the lower turbinate it would only penetrate about ½ cm. The growth, therefore, arose from the lateral wall of the nose and lower turbinate. During the manipulation a drop of pus appeared at the lowest point of the growth, which reappeared whenever it was wiped away; but no opening could be found with the probe. Transillumination was unsatisfactory. An aspirating needle was then introduced into the growth and pus withdrawn. The growth was then incised and two drachms of pus escaped. It then collapsed completely until nothing was left but what appeared as a slight thickening of the posterior end of the lower turbinate. About one-half inch of a probe was then bent at right angles and passed through the opening, directly outward into the antrum of Highmore. No bare bone could be felt. A cannula, similarly bent, was then introduced, and the antrum thoroughly irrigated with a quart of boric-acid solution. These irrigations were repeated daily. After one week the opening had closed. It was again enlarged with a sharp hook and scissors until it was about 1 cm. in diameter. The drainage thereafter was free, and the irrigations were continued every other day until all secretion ceased. The obstructed breathing was relieved, and the swollen turbinates receded, not only on the diseased side, but on the other side also.

As to the diagnosis in this case, as the patient was treated for two years for simple nasopharyngitis only, it becomes necessary to call attention to the fact that secretion from any of the accessory sinuses will flow backward into the nasopharynx if the turbinates are swollen, as they were in this case from the irritating effect of the secretion. The secretion spreads over the nasopharynx, and in blowing the nose may be driven out through the other side, and its presence in the nasopharynx and pharynx sets up a secondary catarrh. The symptoms of this secondary nasopharyngitis may be the only thing of which the patient complains.

The interest attached to this case lies in the fact that an abscess condition could remain for so long a time unrecognized, and in the effort of nature to throw it off. The condition that here arose, a bulging inward of the middle meatus, with either a congenital absence of the bony wall or a necrosis thereof, is one of the rarest conditions in diseases of the antrum of Highmore, according to Gruenwald. Zuckerkandle says that not infrequently the bony wall of the antrum is absent over a large area, there being only the mucous membrane between the antrum and the nose, and in these instances the partition may bulge inward and come in contact with the septum. Hartmann describes such a case (*Deutsche medicinische Wochenschrift*, 1889), and Hajek (Nebenhöhlen der Nase) refers to a similar condition.

In the case here related the drop of pus, the direction taken by the probe, and the subsequent subsidence of the growth on evacuation confirm the diagnosis.

73 EAST NINETY-SECOND STREET.

*Read before the Metropolitan Medical Society, April 27, 1903.

---

**The Use and Abuse of the Nitrites.**—A. B. Greiner classifies the nitrites as circulatory depressants. Nitroglycerin is one of the useful agents in chronic nephritis, because it dilates the renal vessels and takes resistance from in front of the heart by the depressant effect on the vasomotor system. To certain disorders of the circulatory system do we find the nitrites particularly applicable—their therapeutic usefulness may be said to be confined to those conditions accompanied by vasoconstriction; and distinctly contraindicated when the symptoms are produced by vasodilatation or are dependent upon it. Angina pectoris is amenable to the nitrites because of the power to produce dilatation of the vessels. In fainting, the circulation to the vital centers in the medulla should be restored or improved. Nitrites increase the anæmia of the vital centers, yet they are often administered. A better understanding of these drugs is desirable on account of the different views regarding their applicability.—*Virginia Medical Semi-Monthly*, July 10, 1903.

**The Value of the Leucocyte Count in Gynecological Conditions.**—M. Dütsmann reports a series of two thousand leucocyte counts made in patients suffering from pelvic conditions. In the main his results corroborate the statistics of other authors, but he lays especial stress on the prognostic value of repeated counts. In all severe infections, when the leucocyte count drops, while the clinical condition remains unimproved, the organism is losing in its struggle against the infection and the chances of recovery are bad. This is particularly true in puerperal sepsis, and if it is found that after a chill or sudden rise of temperature the leucocytes do not exhibit a corresponding increase, the situation is becoming critical and heroic treatment, *e.g.* hysterectomy, is indicated. The iodine reaction strengthens the conclusions drawn from the leucocyte count, and is of service in confirming a diagnosis. Large ovarian cysts, especially with twisted pedicles, exhibit a leucocytosis without the presence of pus, owing to the peritoneal irritation caused, but do not give an iodine reaction. The most interesting part of the author's communication is concerned with his study of eclampsia. As in septic conditions a normal or subnormal count is of infaust significance and such patients die of the disease, while with a continuously high count the seizures abate in violence and frequency and recovery ensues. This behavior of the resisting forces of the organism adds color to the modern view that eclampsia is an infectious disease.—*Monatsschrift für Geburtshilfe und Gynäkologie.*

## DISCOVERY OF A PROTOZOAN PARASITE IN THE YELLOW-FEVER MOSQUITO.

FINLAY'S claim in 1881 that infection of yellow fever occurs by means of the mosquito was not taken seriously until after the demonstration of a like mode of transmission in the case of malaria. In 1900 and 1901, however, Reed, Carroll, Lazear, and Agramonte demonstrated this mode of infection for yellow fever, and showed also that fomites do not convey infection, but that the disease can be communicated by inoculation with the blood of the sick. They also, as Finlay had done before, designated *Stegomyia fasciata* as the intermediate host.

The experiments made by Major Reed and the other members of the United States Army Board in Havana were last summer repeated and extended by Drs. Parker, Beyer, and Pothier, members of the Yellow Fever Institute of the Public Health and Marine Hospital Service in Vera Cruz, and in the report of their labors, published in Bulletin No. 13 of the Yellow Fever Institute, the important announcement is made of the discovery of the probable parasite of yellow fever. These investigators worked in association with a commission appointed by the Mexican Government, Drs. Matienzo, del Rio, and Iglezias. A non-immune from a mountain village, who had never before visited the coast and who for the preceding twenty-two months had been in jail, was examined physically and found free from organic disease. The urine and blood examinations were negative. On September 4 two mosquitos which had fed on a patient ill of yellow fever on August 13, forty-one and a half hours after the chill, were permitted to bite his left hand. Seventy-four hours later yellow fever developed. On September 8 mosquitos were allowed to feed on his hands, and were then killed and examined histologically. The mosquitos whose bites produced the disease showed, on microscopical examination, in their salivary glands the spores filled with sporozoites in various stages of maturation, and the mosquitos infected by feeding upon the patient showed, on the fifth day after feeding, the conjugating bodies described below. The next case was in a man who had lived all his life in a mountain village, except for thirty days in Vera Cruz some eight years before. On September 9 he was inoculated with blood drawn from the preceding patient which had been defibrinated and diluted with two volumes of salt-solution and passed through a Berkefeld filter. No symptoms appeared until the nineteenth day when he developed yellow fever. This the authors think it more reasonable to assume was due to some accidental infection (from a mosquito) than to admit an incubation period of nineteen and a half days. At any rate another non-immune inoculated with another portion of the same serum failed to develop the disease. Also a non-immune who swallowed two infected mosquitos crushed up in water remained free from the disease.

The blood changes observed were: An increase in the red cells (from 4,600,000 to as many as 6,000,000, with a corresponding increase in hæmoglobin), due probably merely to dissipation of fluid. The white cells showed no variations in structure, pigment, vacuoles, or fat, but a marked variation in granulation, owing to the almost or quite complete disappearance of the eosinophiles. The blood and the organs post mortem were negative bacteriologically. The serum showed toward B. icteroides of Sanarelli, B. typhosus and B. dysenteriæ of Shiga, and B. còli communis, no agglutinating power.

Several investigators have believed that they had discovered the microorganism causative of yellow fever, but the present authors discovered and worked out the life history and the infection circle of a sporozoon which may possibly be shown to be the causal microorganism. In the stomach and œsophageal diverticulum of mosquitos which had fed on yellow-fever patients the authors found small fusiform protozoa, mostly in groups, though also single, which bore a striking resemblance to the terminal conjugation stages of certain sporozoa. These bodies, after conjugation, pass into the œsophageal diverticulum and undergo further development in connection with an "albuminoid body" of unknown origin and nature; increasing in size, the nucleus undergoing fragmentation or multiplication, and the resulting chromatophile granules rapidly increasing in size and becoming rather sharply defined and less regularly elongate oval, and forming "sporoblasts." These last are later liberated, and, passing to the anterior end of the diverticulum, penetrate the delicate connective tissue septum into the salivary gland, the cells of which they enter. In these cells the sporoblasts break up into resting spores which ultimately find their way into the lumen of the gland ready for discharge. From such infected mosquitos the authors produced yellow fever, as described elsewhere. Then from the patient they recovered the microorganism in mosquitos which had fed on the patient. "As further evidence, we permitted this same species of mosquito, *Stegomyia fasciata*, to feed on a case of malarial fever of the malignant quotidian type, on normal blood and on sugar and water. In none of these mosquitos did we find the parasite.' To this parasite they gave the name *Myxococcidium stegomyiæ*.

The presence of the parasite modifies the life processes of the mosquito so as to provide for the parasite's welfare. Whereas in normal mosquitos following feeding upon albuminous food, which is necessary for ova development, the ova undergo hypertrophy, distending the abdominal cavity, in the infected mosquitos after a primary hypertrophy the ova atrophy. This atrophy, the authors believe, alters the instinct of the insect, and preserves life for some time by suspending the process of ovipositing.

## THE TREND OF MODERN MEDICAL EDUCATION IN THE UNITED STATES.

Discussion on reform of medical education in the United States is constant and persistent. The fact has been for some time plainly evident that there is among a large number of the medical profession grave dissatisfaction with the present anomalous condition of affairs as regards the standard of medical education throughout the country. It is felt that strong efforts should be made to elevate the status of the medical profession in every part of the United States, so that an individual procuring a degree from one State should be upon the same plane as he who qualifies as a medical practitioner in another State.

Dr. David Starr Jordan, President of Leland Stanford, Jr., University, delivered a short time ago an address at the Cooper Medical College Commencement upon the training of a physician, in which he showed that in the United States, so far as medical education is concerned, the parting of the ways has been reached, and that a decision must soon be come to as to the methods to be employed in educating students of medicine in the future. The speaker pointed out that in the continental nations of Europe the teaching of medicine has been from the first a university function. In England, on the other hand, medical instruction has been more or less divorced from the university. It has been rather a function of medical associations and hospitals. The American college was modeled upon the English plan, its first purpose being to develop clergymen and gentlemen; thus the medical school in America arose through associations of physicians, entirely apart from the collegiate system. Some States, however, came to the conclusion that it was cheaper for the State to educate its own physicians than to tolerate uneducated ones.

The University of Michigan was the first State college to act upon this principle, and some other State institutions followed its example. In the meantime, for lack of endowment and public support, medical schools were founded by private enterprise, and later, other schools for purposes of advertising or money-making, sprang up like mushrooms on every side and, as Dr. Jordan said, we had medical schools of every grade of honor or dishonor; some ranking with the best in the world, others periodically raided by the police.

Referring to the trend of modern medical education, the speaker said that "more and more the honest schools are brought into touch with the university. Around the university the tested educational machinery tends to center." The university affords that foundation of science which is essential to the making of a good physician. The university teaches the science and the medical school teaches its application. Dr. Jordan thinks that two great influences are at work, one, that of the university, which tends to push up the requirements for entrance to the medical profession, the other, that of the counting-house and the desire to show numbers, which tend to push them down. Said the speaker, "Shall men go into medicine from the common school; from the middle of the college course; from its end, or shall we, with Johns Hopkins, demand, not only a college course but one which contains all the sciences fundamental to the study of medicine?" And the answer he gives to his own question is as follows: "The practical evolution of this matter will be thus: The medical school for the exceptional student will require a college course of science with physiology and chemistry as the leading subjects, other sciences, with German and French, being necessary factors. The State medical colleges and those of similar purpose will content themselves with a minimum of two years of college work along semi-professional lines, the preparatory medical course." Undoubtedly the university will play a more important part in medical education than it formerly has, but until some kind of uniformity in the standard of medical education has come into force in all or the greater part of the country it is of little use to map out a scheme for the training of the American medical student, considered as a whole. The first and greatest need is a uniform standard of medical education in every State of the Union.

---

## SLEEPING SICKNESS AND ITS GEOGRAPHICAL DISTRIBUTION.

Owing principally to the white man's invasion of Africa, this curious disease—almost wholly confined to the African negro—has attracted, of late, much attention. The researches of the Portuguese Commission in Loanda and of a British commission in Uganda, as to the etiology of the disease, were referred to in these columns on June 27. To the *Journal of Tropical Medicine*, July 1, Dr. Louis W. Sambon, the talented Italian, who is a lecturer at the London School of Tropical Medicine, contributes an article on sleeping sickness. Writing of its epidemiology, he says: "The epidemiology of sleeping sickness is as yet very imperfectly known, but it presents several remarkable peculiarities. The disease is strictly connected with water. It prevails only along rivers and streams, or on the shores of lakes. Several persons have remarked that its endemic centers correspond, as a rule, with the worst malaria stations, and Corré lays special stress on the paludal nature of the sleeping sickness centers of Joal and Portudal. In Uganda, where it has only just appeared, it is confined to the northern shores of Lake Victoria Nyanza, and to the adjacent islands. Another characteristic feature is its patchy distribution. The disease is not generally diffused throughout a river valley or other endemic center, but affects particular foci, clings to particular villages, and is not observed in places near by. Corré has frequently remarked that sleeping sickness may attach itself to a particular house. It may suddenly appear in villages hitherto immune and cling to that place for years." Concerning the trypanosoma discovered by Dr. Castellani of the British commission in Uganda, Sambon says: "A comparison between sleeping sickness and the various diseases of animals caused by trypanosoma would seem to favor the belief that Castellani may have discovered the true cause of sleeping sickness."

Dr. Frank G. Clemow, British Delegate to the Ottoman Board of Health, has recently brought out a work on the "Geography of Disease." Writing of the recent geographical distribution of sleeping sickness, he says that "the disease, so far as is known at present, is met with as an indigenous malady, principally along the West Coast of Africa. Its northern boundary appears to be the Senegal

river, while to the south it is limited by the southern border of the Portuguese colonies. It is particularly common in the French colony of Senegambia, and in some of the ports there it has at times been so severe that the extraordinary phenomenon has been seen of a negro garrison being replaced by white troops on account of the losses caused among the former by its ravages."

The disease prevails largely along the shores of the Gulf of Guinea, while it is frequently encountered in Liberia, along the Gold Coast, and at Old Calabar in the Bight of Biafra. In 1901 it was extremely active at Principe Island, and had been so for the previous fourteen years. In the valley of the Congo it had been known for long in endemic form. The malady has even penetrated as far as Stanley Falls, the very heart of equatorial Africa. As mentioned before, the disease has recently gained a foothold in Uganda, where it is wreaking great havoc. In In Southern Africa sleeping sickness prevails extensively in the Portuguese colony of Angola.

Africa is the home of sleeping sickness, but secondary centers have developed occasionally in other parts of the globe, "although," says Dr. Clemow, "it is almost certain that these secondary centers have always owed their origin to importation from Africa." At one time the disease occurred with comparative frequency among negroes who had been transported from Africa to the West Indies, the Bahamas, and Brazil. At the present time, however, the black population of the West Indies and Brazil are said to be completely free from sleeping sickness, but in the Guianas there is some evidence pointing to the fact that it is now endemic in those countries.

Dr. Clemow states that negro lethargy is entirely a tropical disorder, and insists that as an endemic it is strictly confined to the Continent of Africa, between the sixteenth degree of north latitude and the eighteenth degree of south latitude. It is not confined to the coast nor to the western half of the Continent, but is seen in the very heart of the Congo Free State and in Uganda—countries which have no coast line. The statement of Dr. Sambon that the disease always breaks out in and confines itself to the vicinity of water, is not referred to in Dr. Clemow's book.

There is no perfectly authenticated case on record of sleeping sickness in a white man. Ferguson was of the opinion that he had met with the disease in white subjects in British Guiana, but as Uncinaria duodenalis was found in these patients, Ozzard thinks that Ferguson must have mistaken advanced cases of ankylostomiasis for the sleeping sickness. The malady is essentially one of tropical Africa, and in those instances in which it has occurred elsewhere, it had been imported thence. Corré is authority for the statement that in those areas of Western Africa where negro lethargy is endemic, negroes coming from other districts are particularly liable to it, the local inhabitants appearing to become, in a sense, acclimatized.

---

**The Automobile Race in Ireland.**—The average of accidents during the Automobile Club fortnight in Ireland did not reach that of an ordinary driving tour, or a week of racing on the flat. At Cork, an Irishman said, "Sure, it was very successful, but there were no accidents at all." The "but" is delightful.

## The Addresses before the British Medical Association.

The London journals of August 1, just at hand, contain the addresses delivered before the British Medical Association at its annual meeting in Swansea. Our readers are already familiar with the same from the very full and accurate cable report sent by our experienced correspondents, but it may be of interest to refer again to some points not specially emphasized in the reports.

The address of the President, Dr. T. D. Griffiths, dealt with the evolution of antiseptic surgery and the influence of the progress and advancement of bacteriology and therapeutics. The subject chosen was a somewhat well-worn one, but the speaker succeeded in investing it with much interest. The first part of the address was taken up with a sketch of the manner in which surgery was practised in the London hospitals in the days when Dr. Griffiths was a student. At that time the speaker pointed out that the large wards of the hospitals were filled with all sorts of cases indiscriminately —simple and compound fractures, suppurating joints, traumatic, senile, and hospital gangrene, erysipelas, septicæmia, pyæmia, and cases operated on for accidents and diseases, all of which were dressed by the same attendants. No attempt was made at cleanliness, and healthy suppuration, termed "laudable pus," was regarded as a sign of good dressing and healthy action. The wonderful change brought about by the discoveries of Schwann and Pasteur, and their practical application by Lister, rendered possible by his successful investigations into the problem of inflammation and its attendant suppuration in wounds, was briefly reviewed. Reference was made to the need of the establishment of self-supporting nursing institutions to replace private nursing institutes, some of which are now flourishing by imposing on the invalid public, women imperfectly trained as nurses, and also to replace many of the so-called surgical homes.

The subjects of bacteriology and immunity were treated at some length. Therapeutics in relation to bacteriology was likewise discussed, and it was shown that Listerism is as valuable in the practice of medicine as it is in surgery.

The greater portion of the address was devoted to the question of public health, and the neglect of sanitary affairs in rural districts was severely criticised. Dr. Griffiths said he was of the opinion that the time had come when the sanitary condition of urban and rural districts should be improved in order to secure for the public the full benefit of the advance recently achieved in the science of hygiene by bacteriology and the principles of Listerism. Regret was expressed at the attitude of the government with regard to vaccination, and at the tendency of legislation for many years past in the direction of decentralization.

The address in medicine was delivered by Dr. Frederick T. Roberts. At the commencement of his address he took the opportunity to launch a tirade against "the absurd, irrational, and most mischievous specialism which is so rampant at the present day." Dr. Roberts chose as the subject of his remarks "Infective and Infectious Diseases." The speaker reviewed the practical etiology of infectious diseases, and among other facts drew attention to the remarkable light which modern observations and researches have thrown upon the rôle which different animals play in the transmission of infectious diseases. He further stated that he did not think the danger, of infection being carried directly by domestic animals, such as birds, cats, and dogs, from person to person, was appreciated at its full significance.

The morbid anatomy and histology, and the clinical history, phenomena, and diagnosis of infectious diseases were discussed more or less fully. Into the treatment and prevention of infectious diseases Dr. Roberts entered exhaustively. After declaring that we have few novelties in the way of specific remedies, he said he held the view that a very large proportion of cases of acute specific fevers could be steered through their course by the application of practical common sense, and sound physiological, natural, and sanitary principles. As a rule, no active treatment was required, unless it were an occasional aperient. The speaker, however, did not advocate a general policy of "masterly inactivity" in dealing with infectious diseases, but recognized the fact that there are many diseases and cases in which even from the outset the practitioner must admit the necessity of administering in some way or other suitable medicinal remedies.

With regard to hydrotherapy and allied methods of treating infectious diseases, Dr. Roberts did not express himself very enthusiastically. As to the use of alcohol in the same class of complaints, the speaker said that he was a staunch advocate of its judicious administration in a large number of cases. Dr. Roberts, while acknowledging the immense value of serum therapy in the treatment of some complaints, was not the less conscious that this method had entirely failed in others, and that in still other diseases it was as yet on trial.

The address in surgery was given by Mr. A. W. Mayo Robson, who began his remarks by tracing the origin and development of ovariotomy, and showed that from being a most deadly operation it had come to be one attended by few fatal results.

The great success achieved by the late Lawson Tait in operations of this description Mr. Robson attributed to his discovery of the value of natural drainage through the intestines, and the importance of the avoidance of morphine. He made a routine practice of purging after operation, and so avoided that distension which used to kill so rapidly in early ovarian work. The speaker made some caustic remarks on the term "peritonitis," saying that even the present time it was a convenient cloak for ignorance. Acute peritoneal infection he considered a far more rational designation than acute peritonitis, and surgery to be of service in this condition must be prompt. The speaker advised operation in the quiescent period of appendicitis and early operation in the acute type of the disease. With regard to hysterectomy for myoma, Dr. Robson alluded to his own experience in 170 cases of operation, with a 5.2 per cent. mortality. Attention was drawn to the remarkable progress which had been made in the surgery of the bile passages, and it was pointed out that the first cholecystotomy was performed in 1867 by Bobbs of Indianapolis.

The surgery of the stomach was dealt with at some length, and the fact was mentioned that until recently but little success had been met with in this branch of surgery. The greatest advance had probably been made in operating for diseases of the pancreas, the foundation of this form of treatment was laid by the classical experimental work of Senn in 1886. The work of Senn and of Murphy in improving the methods of operating for diseases of the intestines was referred to. Radical operation, performed early, was earnestly recommended by the speaker for hernia, when it was practically devoid of risk. It was also shown that in the hands of Murdoch, Cameron, Leopold, Sanger, and other operators Cæsarean section had been done in recent years with an extremely small mortality, owing to the genius of Lawson Tait, who utilized the post-mortem experience of Bernutz and Goupil, and the clinical observations of J. S. Parry, ectopic gestation had been treated successfully. The work of Kelly of Baltimore, Robson himself, E. Lambotte of Brussels, and Harris of Chicago, had rendered differentiation of diseases of the kidneys much more certain, and in consequence the surgery of the kidneys and ureters had made great strides. Mention was also made of Edelbohls' operation of renal decapsulation.

Mr. Robson concluded his address by pointing out that future progress in surgery would be intimately bound up with the work of the physician, the pathologist and the bacteriologist, but that the trend of modern medicine was to prevent rather than to cure disease.

---

### Suicide in the United States.

In the *Yale Review* for May, William B. Bailey has an article on suicide in the United States from 1897 to 1901. The statistics given are not absolutely vouched for as to accuracy. They are taken almost wholly from the public press, as the Government affords no assistance, and the registration area of the various States is lamentably small. Thirty journals were studied to collect the data supplied by Mr. Bailey. Out of 10,000 suicides 7,781 were males and 2,219 females, giving a ratio of about 3½ males to 1 female. As in most countries the number of the married who took their own lives slightly exceeded that of the single, while single, widowed, and divorced women were found to commit suicide more often than men in like situations. Shooting appears to be the favorite method of putting an end to one's existence in this country, followed closely by poison. Hanging as a means of self-destruction is not held in so much favor as in the northern portions of Europe, nor is drowning, as in the southern countries. Jumping, poison, and gas are confined principally to the cities. With males the favorite method is shooting, and the one least used is jumping; while most women seem to have a predilection for poison a few end their lives by cutting.

In regard to motive, despondency stands at the head of the list, claiming about 20 per cent. of the victims. Business losses, ill health, and insanity follow in the order named, with about 13 per cent. each. Then comes disappointment in love, with the remaining motives far in the rear. Alcoholism is shown to be a factor in the impulsion to suicide among males; indeed a more important factor than the figures of Mr. Bailey would seem to demonstrate. Women are more apt to kill themselves on account of grief than are men, and ill health also tells more heavily upon them. Between the ages of twenty and thirty years the maximum of suicides from grief, chagrin, and from being crossed in love, occur. Between twenty and thirty, too, fall the maxima from alcoholism, insanity, despondency, domestic trouble, and fear of disgrace. From thirty to forty come the greatest numbers from business losses and ill health. Females have a tendency to commit suicide at an earlier age than males. From the data gathered by the writer it would seem that Monday is the favorite day for committing suicide, followed by Sunday. From Monday down to and including Thursday there is a gradual fall, but on Friday there is a sudden rise that cannot be easily explained. Saturday is, next to Thursday, the lowest day in the week. Among the males Monday is pre-eminently the day for suicide, doubtless due to a great extent to the fact that on that day the dissipated workman's money is spent, and he s in the throes of despondency and remorse. Females prefer Sunday to

Monday. The greater number of suicides occur in the twelve hours before noon. Beginning at midnight there is a continual increase until 6 P.M. Suicides on account of ill health and insanity are frequent in the early hours of the morning; alcoholism and chagrin later in the forenoon; despondency in the afternoon; disappointment, love, and family trouble late in the evening. The foregoing figures are curiously interesting if not of especial value.

---

### The Dust from Buildings in Process of Demolition.

The *Lancet* of July 18 has an annotation headed as above, in which it is pointed out that the process of demolishing old brick buildings, and very often new ones too, is always going on somewhere in London, much to the annoyance and discomfort of those who live in adjoining premises, and also of those who pass by. Attention is likewise drawn to the fact that no serious effort is made to suppress the most irritating and injurious dust caused by the housebreaker's destructive operations. In consequence of this neglect of precautionary measures the dust bloweth where it listeth, into persons' eyes and nostrils, and down their throats, as well as settling upon any stationary objects within its range of flight, be they food or garments. Doubtless the dust nuisance is a real one in London, but there are few inhabitants of this city who are not of the opinion that it cannot compare in magnitude with the same evil as exemplified throughout the length and breadth of New York. It may be asserted with little fear of contradiction that in no city, ancient or modern—except possibly a small number which have undergone a long siege—has been witnessed such wholesale knocking down of buildings as is now being carried on from one end of New York to the other. True, the buildings may not be so old and solid in New York as in London, but what is lacking in this respect is more than made up in quantity. Not only, too, is it the destruction of buildings that causes the scattering of the dust by the four winds of heaven, but the construction of the subway, the tearing up of roads and car tracks, all combine to create dust and noise, and to render life in New York under existing condition a continual nightmare.

The remedy suggested by the writer in the *Lancet* is that before the demolition of a house is begun, the walls should be well wetted and the débris watered from time to time. The suggestion is a good one, but it is one thing to pass a law and another to enforce it. This very procedure is, we believe, enjoined by a city ordinance in New York, but that it is not enforced is notorious. Perhaps the authorities fear that if it were attempted to conduct such a project to a successful issue in New York the water supply would fail. Nevertheless, some means should be tried to abate what is both a nuisance and discomfort, and a menace to health.

---

### Birth Rate in Fiction.

The decline of the birth rate in some of the countries of the world, and especially of that among Americans of native stock, has been discussed within the past few months almost *ad nauseam* in the United States. The subject has been written up and argued upon in all sorts of magazines and journals, and although no unanimous decision has been reached, it has nevertheless been generally admitted that native-born Americans do not produce nearly such large families as was the case two or three generations ago. An ingenious delver into matters curious, or possibly somewhat of a wag, has sent a letter to the August number of the *Popular Science Monthly* in which he declares that the birth rate in fiction has been steadily decreasing for a considerable time. The writer calls attention to the low birth rate in novels and plays, and adds that united as it is with a high death rate, will inevitably lead to the rapid extermination of the hero and heroine. He is strongly of the opinion that the birth rate in novels is decreasing, and that while families of a respectable size may be found in Thackeray and Dickens, they scarcely exist in Meredith, Hardy, and James. In order to prove his point the writer refers to two novels—"Vanity Fair" and "Beauchamp's Career." Becky Sharp was an only child. Sir Pitt Crawley, twice married, had four children; his brother five and his sister none, so there was an average family of three. Osborne and Dobbin each had two sisters, and the Sedley family consisted of brother and sister. Matters were yet worse in the next generation. Amelia had two husbands and two children. Becky one child, Sir Pitt one, and Josh none. "This," says the writer, "is apparently an average family of 1.83, which is almost exactly that of the Harvard graduates, according to President Eliot." In "Beauchamp's Career" the families seem to grow smaller by degrees and beautifully less. Twelve married couples have about five children—a truly distressing state of affairs and one that warrants the writer in predicting the rapid extermination of the population of the novel. Novelists of the present day certainly do not, as a rule, introduce large families to their readers. This may be in keeping with the actual condition of things, or it may be that children are as difficult to manage in the pages of a book as they are in real life, and accordingly in both cases they are either not conceived or not brought forth.

---

**Tuberculous Peritonitis in Childhood.**—Alfred Friedlander says that by far the greatest number of the cases of this affection belong to the chronic form. English and American pathologists recognize three types of this form, ascitic, fibro-adhesive, and ulcerative-suppurative. The disease almost always begins insidiously. Anæmia is always suspicious, and if joined to emaciation should put us on our guard. In the vast majority of these cases attention will be directed to the abdomen, either because of pain, or because objective examination will reveal abnormal conditions in this region. The occurrence of marked ascites in childhood is always a grave sign. The temperature may run a very irregular course; fever may be entirely absent for weeks or months, or it may range from the normal to 102° or over. The bowels are often constipated, or there may be diarrhœa. The diagnosis of tuberculous peritonitis is often a matter of extreme difficulty. If one hesitates to resort to laparotomy, when there is ascites the withdrawal of fluid may be of value; the cytological examination shows the same characteristics that are found in tuberculosis of other serous membranes. Predominence of the mononuclear lymphocytes points strongly to tuberculous inflammation, while excess of polymorphonuclears is evidence of a purulent inflammation. Another aid to diagnosis is the use of tuberculin. As to treatment, laparotomy is of undoubted value in many cases, especially when there is localized abscess. But its routine employment is not to be recommended. In simple cases, either of the ascitic or fibro-adhesive variety, the attempt should be made to strengthen the patient's resistive powers and to improve his general condition.—*The Cincinnati Lancet-Clinic.*

# News of the Week.

**Bucks Co. (Pa.) Medical Society.**—At the annual meeting held at Quakertown on August 6, Dr. J. B. Carrell of Hatboro read a paper entitled "Success in the Practice of Medicine," and Dr. James N. Raudenbush of Philadelphia a paper on "The Treatment of Tetanus and the Use of Tetanus Antitoxin."

**Smallpox Still Increasing in Philadelphia.**—For the week ended August 8 there were reported to the Philadelphia Board of Health thirty-six cases of smallpox with five deaths. Active measures have been taken to prevent an extensive epidemic and vaccination has been undertaken on a large scale. Almost all of the cases have occurred in unvaccinated individuals.

**Municipal Hospital, Philadelphia.**—Dr. B. Franklin Royer, at present demonstrator of anatomy in Jefferson Medical College, has been appointed chief resident physician in the Municipal Hospital.

**Proposed New Journals.**—The American Orthopedic Association will publish early in August the first number of a new quarterly, *The American Journal of Orthopedic Surgery*. It will replace the Transactions, formerly published by the association. The journal will contain the papers read by members at the annual meeting, together with such discussion as took place upon them. In addition to these, original papers on orthopedic subjects by members and from outside sources will be published. The journal will also contain abstracts of important orthopedic books and articles appearing here and abroad. It is intended to develop this department, especially in its survey of foreign literature. The editorial committee consists of Drs. R. W. Lovett of Boston, B. F. McKenzie of Toronto, and H. M. Sherman of San Francisco.

Another new journal, which is announced to appear in October next, is to be what its name implies, *The Daily Medical Journal*. Each issue will consist of six pages. The managing editor will be Dr. M. W. Curran of New York.

**The Nova Scotia Medical Society held its thirty-fifth annual meeting at Antigonish on July 1 and 2, under the presidency of Dr. J. J. Cameron. Dr. Henry C. Marcy of Boston delivered the annual Address in Surgery, and Dr. G. G. Campbell of Montreal the Address in Medicine.**

**A National Relief Society.**—Miss Clara Barton, against whose continuance as head of the American Red Cross Society very determined opposition has recently developed, proposes the creation of a national relief association with branches in every city in the United States. She suggests that a national fund be established to be at ready command of a finance committee of men of national reputation when calamity breaks upon the country. It is her aim to establish central executive offices from which will be directed an educational movement in the direction of popular instruction in first aid to the injured. Out of the national fund permanent executive offices may be built, which shall be the home of the national organization.

**The New Bellevue Hospital.**—It is announced that certain difficulties which had been encountered in connection with the acquisition of the block between Twenty-eighth and Twenty-ninth streets, running down to the East River, upon which it was proposed to build the new Bellevue Hospital, have been disposed of, and that the way is now clear for the Department of Charities to acquire the land. In all probability work will be begun on the new buildings for the hospital in October. It is planned to start building at the northern end of the site, the Twenty-ninth street end. As soon as one building is ready for occupancy, one of the old ones will be torn down, and so on until all the old buildings have been removed. The cost of land to be acquired and the sums to be spent to put it in condition for building will amount to about $2,000,000. The site will comprise the lots from Twenty-sixth to Twenty-ninth streets, and from First avenue to the East River.

**A French Congress against Alcohol.**—The first National Antialcohol Congress will be held in Paris from October 26 to 29, under the honorary presidency of M. Casimir-Périer. The program consists of two parts—the first part of the program will be devoted to a review of the existing situation in regard to alcoholism and the struggle against it; the second to the plan of campaign; this will include the action of the State and local authorities, the medical profession, the clergy, etc., the institution of an educational propaganda among young people, and the securing of the powerful influence of women. The Congress will also discuss the organization of a campaign against alcoholism by means of the federation of all temperance organizations directed by a permanent committee.

**A Reverend Health Officer.**—The Board of Health of Pottsville, Pa., has appointed the Rev. W. D. Williams, pastor of the Congregational Church, health officer of the town.

**New Building for the Manhattan Maternity Hospital.**—Plans for a new building to be erected on East Sixtieth street for the Manhattan Maternity Hospital have been filed with the Building Superintendent. The structure is to cost $58,000, and will be of ornamental brick, 45.3 feet front and 66.3 feet deep, on a lot 100x100.3 feet. It will be four stories high and fireproof throughout. There will be four wards (one for babies), four isolating rooms, a diet kitchen, an operating room, and an amphitheater.

**Col. Henry Lippincott** of the Army Medical Corps, who was among those designated to be appointed brigadier-general and placed on the retired list, will not be promoted. The reason given for this is that Colonel Lippincott did not have a civil war record of one full year, a necessity to secure the right to promotion according to the President's direction. The matter was called to the attention of the War Department, and referred to the President, who gave directions to have Colonel Lippincott's name taken from the list.

**Father Operated upon Son.**—A young surgeon in Brooklyn has just recovered from an operation for appendicitis performed by his own father. This unusual occurrence took place, it is said, at the urgent solicitation of the sick son, whose confidence in the superior skill of his parent—a confidence shared by many others—was thus happily justified.

**Health Inspectors Punished.**—As a result of charges of neglect of duty which were preferred against ten medical inspectors of the Department of Health in Brooklyn, three have been dismissed, four fined, and one censured. Two were exonerated. The charge in each case was that the inspector permitted the disinfection of premises where contagious diseases had occurred, before the termination of the disease. Each inspector received a salary of $1,200 a year.

**The Philippine Opium Commission.**—Governor Taft has appointed Major Edwin C. Carter, Bishop Brent, and Dr. Albert a commission to visit countries where opium is used and ascertain the methods of regulation and control. The commission is to visit Japan, Formosa, Shanghai, Hongkong, Singapore, Java, and Burmah. An investigation of this kind is thought necessary on account of the opposition which has developed to the proposed bill for the regulation of the opium traffic in the Philippines.

**A New Dispensary and Infirmary.**—The Sydenham Society has founded a hospital and dispensary at 347 East One Hundred and Sixteenth street, New York. The dispensary is situated on the lower floors, and on the upper floors there are twenty beds and an operating room. Drs. Salo Cohn, R. Cronson, J. Goldstein, H. Jarecky, R. Kunitzer, J. Levin, L. Lichtschein, S. Mark, and L. Marcus compose the visiting staff.

**Cause and Cost of Typhoid Fever in the Boer War.**—The report of the commission which investigated the prevalence of dysentery and typhoid fever among the British forces during the South-African war fills a bulky Blue Book, which was issued August 8. The commission finds that flies were the active agents in the dissemination of typhoid fever in standing camps, although the comparative immunity of the Boers is attributed to the boiling of their drinking water. It is calculated that the widespread occurrence of typhoid fever during the war entailed an expenditure of upward of $20,000,000.

**Lake Keuka Medical and Surgical Association.**—The fourth annual meeting of this society will be held at Grove Springs, Lake Keuka, N. Y., on Tuesday and Wednesday, August 11 and 12, 1903, under the presidency of Dr. Arthur W. Booth of Elmira, N. Y. The secretary and treasurer is Dr. W. W. Smith of Avoca, N. Y.

**A Memorial to the Late Major Reed.**—A meeting has been called at Bar Harbor, Me., to consider the project of a memorial in honor of the late Major Walter Reed, M.D., U. S. A., to whom the world is indebted for most important services in the investigation and the suppression of yellow fever. Leading professional men have been invited to be present. Several committees in different parts of the country have already been appointed, and the object of this conference is to secure unanimity of purpose and concerted action. Addresses may be expected from gentlemen who are well acquainted with all the facts. The committee calling the meeting consists of Drs. Daniel C. Gilman, S. Weir Mitchell, Edward G. Janeway, Wm. H. Welch, and Christian A. Herter.

**Dr. Lorenz in Mexico.**—A correspondent of the Vienna *Zeit* writes that, notwithstanding the honors heaped upon Prof. Adolf Lorenz in the United States, hardly any attention was paid to him in Mexico. He was not invited to demonstrate his method, and the local German as well as the Mexican doctors kept aloof from him. The Austrian ambassador, Count Hohenwart, however, gave a dinner in his honor.

**Canadian Medical Association.**—The thirty-sixth annual meeting of this society will be held in London, Ont., on August 25, 26, 27, and 28, under the presidency of Dr. R. H. Morehouse of London. The address in surgery will be delivered by Dr. James Stewart of Montreal, the address in medicine by Dr. Alexander Hugh Ferguson of Chicago, and the address in gynecology by Dr. Matthew D. Mann of Buffalo.

**Milk Inspection in Pennsylvania.**—As a result of several deaths attributed to milk poisoning an investigation of the dairies of the State was recently undertaken by the Pennsylvania Dairy and Food Department. A thousand samples of milk were analyzed and over 750 of them were found to contain formaldehyde or other antiseptic additions. Many samples of cream also were found to be artificially thickened and made a deep "cream" color by the addition of anilin dyes.

**Insanity in England.**—The annual report of the Lunacy Commissioners, abstracted in a cable despatch to *The Sun* of August 2, shows an enormous increase in madness in England and Wales. In 1859 the number of insane was 36,762, or one in 536 of the population. There has been a steady increase from that time up to January 1, 1903, when the number of insane was 113,964, or one in every 293 of population. The rate of increase since 1894 has been especially notable, the number at that time having been 92,067. There was never such an increase in the numbers of insane as in the year ended December 31, 1902, the increase over the previous year being 3,251. The number of persons who lost their minds in 1902 alone was 22,581, or almost 500 per week. The increase is found almost entirely among pauper lunatics. The proportion of lunatics privately cared for to the population is about the same now as it was in 1859, whereas the pauper proportion is twice as high. Among the causes of lunacy in the cases tabulated by the commission, the most prolific was the abuse of alcoholic beverages, 23 per cent. of the male and 9.6 per cent. of the female cases being ascribed to this. The influence of heredity was demonstrated in 24.6 per cent. of the female and 18.8 per cent. of the male cases. Physical rather than mental factors were responsible for the greater number of cases in which the cause could be traced. The increase in insanity was greater in rural districts than in the large cities.

**State Medical Examinations.**—At the recent medical licensing examination in Pennsylvania, of 392 applicants, one was expelled for drinking, two withdrew on account of illness, and 51 failed to pass the examination. In Ohio, out of 91 applicants, eight failed to attain the necessary percentage of 75 marks.

**Influenza in New York State.**—The bulletin of the State Board of Health for July contains a review of the mortality from influenza during the first half of the present year. On the basis of the reports for the months of January to June, inclusive, the review concludes: "The first decade of life, and, in fact, the first twenty years, seems to be almost immune to the effects of the disease, and the middle period of life, to the age of forty-five or fifty, is resistant to it so far as reported fatality is an indication. The susceptible age of infancy is an apparent exception, as more deaths are ascribed to it in the first year than in the next twenty. Prior to the age of fifty only one-fourth of these deaths occurred; after which there is a marked increase in each decade, the greatest number falling between seventy and eighty. The months of December, January, February, and March, during which influenza is prevalent, have much larger mortality at seventy years of age and over than the remainder of the year. There are considerably fewer deaths of males than females, and this is true of every decade except during the first year of life, and especially true in old age."

**Medical Work of the Bahama Geographical Expedition.**—An expedition sent out some time ago by the Geographical Society of Baltimore for a survey

of the Bahama Islands, returned last week. The medical members of the expedition made a study of the diseases prevalent on the islands, and found the health conditions good except for large numbers of lepers and the lax methods, or rather absence of all method, in caring for them. An important and interesting work undertaken by the medical staff was an investigation of the Culicidæ; they found several species of mosquito, among them Stegomyia fasciata, the carrier of yellow fever.

**The Geneva Convention of the Red Cross Society.**—Announcement is made that the convention of the Red Cross Society, which was to have been held in Geneva on September 15, has been indefinitely postponed. The reason given for the postponement is that so many countries have failed to appoint official delegates that it would be impossible to have a representative meeting on the date set.

**Obituary Notes.**—Dr. Moses Bruckheimer of Washington, D. C., died at his home in that city on August 7, aged sixty-two years. He was born in Kilsheimer, Baden, Germany, and came to America when twenty years old. He served throughout the civil war as a member of Company F, Sixth New York Volunteers. At the close of the war he studied medicine and was graduated from the Medical Department of the Columbia University in 1868.

Drs. Adolph Cudell and Ernest H. Luete, two young Cleveland physicians, were drowned in Lake Erie, off the German-American Clubhouse, on August 5. The two young men had procured a boat, and, rowing a short distance into the lake, entered the water. Suddenly one of them was seen to throw up his hands, while the other was swimming toward him. Before aid from the shore could be given, however, both had disappeared.

Dr. Julius A. Schuylke, one of the leading physicians of Wyoming, died suddenly in a Casper-Thermopolis stage while *en route* to Casper on August 7. Death, it is said, was caused by an overdose of some drug. Dr. Schuylke served in the Cuban and Philippine campaigns as surgeon in the army.

Dr. George W. Rolerfort, a prominent negro physician in New Jersey and a Republican politician in Essex County, died in Newark on August 6, of apoplexy, having been stricken the previous afternoon while at the City Almshouse, of which he was medical supervisor. He had practised in Newark for thirteen years and had built up a large practice. He was born at Lexington, Va., on June 20, 1860. By working as a barber and as a waiter he made enough to pay for the first part of his education at Morgan College, Baltimore. For a three years' course at the Leonard Medical School of Raleigh, N. C., from which he was graduated in 1889, and for a special course in gynecology at the University of Pennsylvania a patron supplied the funds.

Dr. E. Virginia Baker Norton died at Lancaster, Pa., on August 5, at the age of fifty years. She was graduated from the Woman's Medical College of Pennsylvania and subsequently became associated in a professional capacity with a State institution at Augusta, Me.

Dr. Thomas J. Yarrow died at Philadelphia on August 6, at the age of sixty-three years. He was thrown from his carriage ten months ago by an unruly horse, and had not been well since. He was graduated from the medical department of the University of Pennsylvania in 1861, and served in the United States Army.

Dr. Richard K. Brown died at Mt. Holly, N. J., on August 8, at the age of sixty-three years. He was graduated from Jefferson Medical College in 1862 and served with distinction as a surgeon during the civil war.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

VACATION — SWANSEA — GENERAL MEDICAL COUNCIL'S FRUITLESS SESSION—OPHTHALMIC NEONATORUM; VIEWS ON ITS PREVENTION BY OBSTETRICIANS AND OCULISTS—DR. ALFRED HILL—OBITUARY.

London, July 24, 1903.

The summer session is practically over. Our talk is of holidays, change of air, and so forth. Some have already set out on their trips; a few are just concluding them, and will wind up at Swansea next week. A much larger number will begin there, for in that town is the meeting of the British Medical Association, lasting through the week, after which there will be a dispersion in all directions. Swansea is not a place I should select for a holiday, but there are many attractions around it, as you may suppose from its position in beautiful South Wales. Geologists are interested in its great undeveloped coal field. Others regard it as the great center of metal works, many as the future ocean port. Antiquaries will turn to the castle, which dates back to 1099, or the queer, narrow streets, now invaded by trams and electric lights.

The trade of Swansea is perhaps the most important of the Bristol Channel ports, exceeding them all in value though not in tonnage. The variety of its imports and exports is remarkable. The Harbor Trust is in such good credit that it can borrow at 3½ per cent., although its debt exceeds £2,000,000. The trustees are placing a steamer at the disposal of the medical visitors, who will thus be able to see the coast to advantage. The railway facilities are unusually great, and doubtless many will seize the opportunity of making or renewing acquaintance with some of the lovely localities of South Wales.

The Medical Council has once more exhibited its pusillanimity and vacillation. Finding the Royal Colleges still recalcitrant, you know that it called this special meeting with a view of representing them to the Privy Council unless they gave way. The resolution to do so was brought forward by Sir Victor Horsley and was to be fully considered at this meeting. Well, the special meeting has come and gone; the discussion—if two days of inconsequent talk deserve the name—has ended as so many proposals in the council have ended, in postponement. The session, called at enormous cost, to settle everything in dispute, has settled nothing. The colleges put their own construction on their charters and hold that the acts of Parliament do not affect them, and so the council has no power to enforce its views. But these acts require the Medical Council to represent to the Privy Council any corporation whose examinations are not satisfactory. Of the insufficiency of the preliminary school examinations instituted by the colleges the Medical Council has abundantly satisfied itself and yet has failed to do the duty imposed upon it.

When it was determined to hold this special session many thought that led by Sir V. Horsley the council would at last take its courage in its teeth. I have watched the doings of the council for years and predicted that it would find a way out of decisive action. The colleges acknowledge the council may criticise their doings—say it is "a criticising body" only, and as such they will take its observations into consideration. The net result of the special session is to put off the matter until November, when perhaps all the old speeches will be repeated and ——? In the meantime the president and a small committee are to confer with representatives of the colleges, "should it appear that a conference on the question raised is desired." And so the council is being reproached by all medical reformers in that it obviously knows its duty but has not the courage to do it.

Ophthalmia neonatorum is so destructive to sight that it probably accounts for 10 per cent. of the cases of blindness, and yet it is a preventable disease. The subject has been brought before the Obstetrical Society by Mr. Sidney Stephenson, who has had special opportunities of studying it. Out of 1,498 cases, gonococci were demonstrated in 60.17 per cent. Various other organisms were sometimes associated with it. He pointed out the fallacies of clinical diagnosis and the necessity of bacteriological examination of the pus from the conjunctiva. Mr. Stephenson urged the advantages of Credé's method of preventive treatment and only admitted one drawback—the production of trivial conjunctival catarrh. Protargol and corrosive sublimate were good, but the 2-per-cent. solution of silver nitrate was, he declared, much better. This Credé treatment was also favored by most of the speakers, though some of the objections were freely discussed.

Dr. Herman admitted the superiority of the silver solution had been shown by Mr. Stephenson's figures, but said that from the mother's point of view the irritation of the conjunctiva was no trifle, and a young practitioner would be injured if it got abroad that he always did something to a baby's eyes which made them sore. He suggested that silver should be used in any case with a history or symptoms of discharge; in others sublimate.

Dr. Walter Swayne felt the same objection, and therefore at the Maternity Charity, which was worked by students, they used sublimate.

Mr. E. Treacher Collins remarked that new-born infants did not secrete tears, but any irritant introduced would cause a copious secretion which would wash away infective matter. The tears, too, were bactericidal, and even clean water introduced at birth had been proved to diminish the cases of ophthalmia, which might be entirely prevented by disinfectant fluids. The disease could also be cured if treated early enough.

Dr. Griffith hoped Mr. Stephenson's paper would convince the council of the society of the necessity of revising its directions to midwives. Imperfect results showed that the method had been improperly carried out. In private practice, however, he only used silver when he suspected infections; in other cases he cleansed the eyelids, nose, and lips with 1 in 1,000 solution of mercuric iodide as soon as the head was born, before the child opened its eyes or attempted to breathe. He considered mercurial solutions of 1 in 2,000 or less untrustworthy, and boric-acid lotions as little, if any, better than water.

Dr. Cullingworth, who is on the Central Midwives' Board, said the rules proposed were now before the Privy Council and he hoped they would be found satisfactory in this respect. He deprecated overburdening the midwife's bag and perhaps her mind with more than one solution. He drew rather a lugubrious picture of the midwife's suffering from the ridicule of the ignorant at her antiseptic basin and phial of eyedrops. But if he inquired in the most ignorant districts I am sure he would find that babies' eyes were often subjected to dangerous, even filthy, washings as a result of superstitious practices. He also remarked that many chemists believed that ionization occurred only in simple watery solution of one mercurial salt, and as antisepticism was due to that, the common solution of biniodide with the aid of potassium iodide was probably inefficacious. This would have to be cleared up—perhaps by bacteriological investigation.

Dr. Amand Routh was much impressed with Mr. Stephenson's paper, but felt a difficulty in recommending two solutions, and there were points against changing the rules of the society. The sublimate was always at hand and silver solutions did not keep well. The rules required the midwife to send for a doctor on the least appearance of inflammation in the child's eyes.

Dr. Horrocks questioned the estimate of 10 per cent. of children affected, especially when modern aseptic midwifery was practised. Even at that ratio the routine recommended would subject 90 per cent. to instillations of germicides of no use to them, and to some of them probably injurious. Why not make a selection and treat only suspected cases? General practitioners were quite capable of doing so.

Dr. Boxall urged routine measures of prevention. Ophthalmia was so disastrous that if the incidence were only 3 instead of 10 per cent. he would advocate them. Thoroughly flushing with 1 in 4,000 sublimate would probably carry on the conjunctival surface as much antiseptic as 1 mm. of a 1-per-cent. solution dropped in, and would also wash away any material from between the lids.

Dr. Sikes thoroughly agreed with Dr. Boxall. The supposed difficulty of detecting the gonococcus did not exist; on the contrary, he had found it to be easy, and early bacteriological examination should be made in every case of sore eyes in new-born children.

Dr. Cuthbert Lockyer maintained that Credé's method was so effectual and the "reaction" so unimportant that its routine employment should be universal.

Princess Henry on Monday opened the new buildings of the Belgrave Hospital for Children.

Dr. Alfred Hill, who lately resigned the Medical Officership of Health to Birmingham, after forty years' work for the corporation, has received a handsome testimonial, and his colleagues in the service have presented him with a silver tea and coffee set.

Alderman Walmsley, J.P., Consulting Surgeon to Salford Royal Hospital, died on the 16th inst., aged seventy-five years.

Mr. Robt. H. Woodhouse, M.R.C.S., L.D.S., died suddenly on the 8th inst. He was a leading dental surgeon, president of the Odontological Society in 1896. He had suffered from heart disease for some years.

**Malaria in Temperate Climates**—Theobald Smith took as his subject for the Shattuck Lecture delivered on June 9, 1903, before the Massachusetts Medical Society, "The Sources, Favoring Conditions, and Prophylaxis of Malaria in Temperate Climates, with Special Reference to Massachusetts," of which the following is a summary: (1) There is no evidence that any but the tertian form of malarial fever can be propagated in Massachusetts. (2) The original source of tertian infection must be looked for in the blood of individuals coming from permanently infected localities in our own country and in Southern Europe. (3) There is no definite information as to the stage of disease or relative immunity in which mosquitos may become infected, but analogy with similar diseases of animal life indicate that the gametes are not formed early in the disease, and that relatively immune persons are the most dangerous, especially after fresh exposure, because in them gametes form very promptly without causing much or any clinical disturbance. (4) The dissemination of infection is most easily promoted in our latitude when people live in a crowded condition, unprotected from mosquitos and near breeding places of Anopheles. (5) The decline and disappearance of malaria after importation and epidemic prevalence is in part due to relative isolation of the inhabitants and protection by quinine and from mosquitos, and in part to the absence of persons partially immunized by long exposure in endemic localities. (6) There is some evidence that sewage pollution in surface waters favors mosquito larvæ directly, through increase in food supply; indirectly, by injuring their enemies. (7) Since malaria may be latent and hence unrecognized, and since it is largely a disease of the lower classes whose movements it is difficult to control, the best method of reaching it is to suppress the mosquitos whenever possible. (8) Malaria is of sufficient importance to become a notifiable disease. (9) Infants and children exposed should have their blood examined during any disturbance of health. (10) In times of epidemic malaria it may become necessary to make special regulations governing infected persons. (11) It is of great importance that the relation of the widely distributed species, *Anopheles punctipennis*, to the parasite of tertian fever be accurately determined. (12) It is also highly desirable to test the infecting power of fresh cases of tertian fever as compared with relapses and with individuals from malarial countries.

*Journal of the American Medical Association, Aug.* 8, 1903.

**Condition of the Endometrium in Cases of Uterine Myomata.**—Thomas S. Cullen gives in this brief paper the results based on gross or histological examination of nearly 1,000 cases. As a rule, the cervical mucosa shows no change. Endometritis is occasionally found, and then is associated with inflammatory changes in the adnexa. Adenocarcinoma of the body of the uterus is frequently associated with myomata. Most of the changes observed in the uterine body are, however, entirely mechanical. Thus portions of the mucosa may be forced into the cavity, producing polypi. The author lays down the general rule, that when the Fallopian tubes are normal and no sloughing submucous myoma is present the uterine mucosa will be normal or show only mechanical changes. Under such favorable conditions the surgeon may do a myomectomy, opening, if necessary, a large part of the uterine cavity, with little danger of infection.

**Control of Suppuration in the Anterior Segment of the Eye by the Insertion of Iodoform into the Anterior Chamber.**—E. C. Ellett reports some experiments and one clinical case bearing upon this method of treatment. The iodoform is used in the form of rods of gelatin containing 50 per cent. of iodoform. These substances are mixed hot and poured on a clean tin plate to harden, and the resulting film is then cut into the required sizes. Under local anæsthesia a peripheral incision is made in the cornea, and the rod is completely inserted into the eye. To be of any value this treatment must be used not later than the second day after infection, and should be repeated daily until positive improvement or absolute failure is noted. The results have not been very brilliant, but, in view of the almost hopeless nature of these cases, they are at least encouraging.

**Albuminuria in Diabetes Mellitus; Its Importance as a Factor in the Causation of Diabetic Coma.**—Arthur R. Elliott draws attention to the importance of albuminuria in diabetes, and insists that it is never without significance. It is either toxic or degenerative, and occurs at some time or other in one-third of all cases of diabetes. Toxic albuminuria is usually acute, and develops in the later stages as a result of the presence of acid

toxins in the blood and urine. It is of the gravest prognostic significance, because it invariably precedes and accompanies diabetic coma; indeed, with the associated renal changes, it is the final determining cause of the coma. Degenerative albuminuria is a very frequent accompaniment of the mild type of diabetes, being due to a secondary nephritis arising from prolonged hyperfunction and impairment of renal nutrition. This form of albuminuria, therefore, has little immediate significance, although it points to the presence of chronic nephritis as a complication.

**Subtropical Trachoma, and a New Remedy in Its Treatment.**—Ruffin A. Wright describes under this title a rather mild type of the disease, and one which the negro almost wholly escapes. The author advocates the use of a five-per-cent. ointment of copper citrate, although believing that a ten-per-cent. ointment will be readily tolerated so soon as excessive secretion has been allayed by one of the silver salts. This treatment appears to have originated with F. R. von Arlt, but it has not been used before in America. Emphasis is laid upon the fact that it does not cure trachoma more quickly than other non-operative methods, but possesses the very great advantage of causing so little pain that the patients readily submit to daily home treatment for a long period. Another claim made for it is that it produces absorption and disappearance of granulations and hypertrophied papillæ quite as rapidly as other applications. The majority of patients will tolerate the application twice a day. A good plan is to apply the remedy at night, letting it remain in the eyes during the night. Its use is contraindicated when there are corneal ulcers or iodine preparations are being used either externally or internally.

*The Medical News, August* 8, 1903.

**The Choice of Technique in Operating upon Prostatic Obstruction.**—Charles H. Chetwood groups the cases of of vesical insufficiency due to obstruction by an enlarged prostate into three classes: In the first class there is simple obstruction, in the second obstruction with inflammation behind it, in the third obstruction, inflammation and secondary degenerative changes. The object of operation in the first class is to remove the obstruction, and in removing it to do so permanently. In the second class, the same object is held in view with the further purpose of draining the inflamed viscus. In the third class, nothing more can be done than is done in the second; and it is sometimes not possible by means of operation to affect the advanced degenerative changes which occur late in these cases.

The choice of operation for the relief of any of these conditions lies at the present time between prostatectomy by lobular enucleation and prostatotomy by means of galvanocautery incisions. As a result of his experience in forty-five cases, the writer comes to the conclusion that prostatotomy is less dangerous than prostatectomy; that it is the operation of choice in a large number of cases of prostatic obstruction, notably those of moderate glandular enlargement, orificial hypertrophy, and contracture, in which the prime object is removal of the obstruction and depression of the bladder orifice; that galvanocaustic incisions, when combined with perineal cystotomy, accomplish satisfactorily the desired result, shorten the operation, and minimize its dangers.

*New York Medical Journal, August* 8, 1903.

**Rheumatism and Typhoid in Childhood.**—J. R. Clemens points out the striking similarity in the clinical picture of rheumatism and typhoid in childhood. Often there is a continued fever at night with general amelioration of symptoms by day, terminating in an apparently rapid convalescence, only to be followed by a marked and persistent anæmia and the development of chorea. An examination of the heart at this time may reveal the presence of a variety of murmurs, and careful inquiry into the previous history will probably elicit recollections of a stiff neck or of "growing pains."

**Some Further Remarks and Queries Concerning the Influence of Altitude upon Heart Disease.**—Robert H. Babcock refers to his previously expressed opinion, that the effects of high altitude upon cardiac disease are to be attributed to the acceleration of the circulation incident to lowered atmospheric pressure, and then cites several cases to show that the subject is a more complex one. Theoretically, residence in a high altitude should be contraindicated in mitral and aortic stenosis, yet in two or three of the cases narrated the patients were in better health in the mountains of Colorado than when at the sea level. The ease with which cardiac strain may be induced at high altitudes is touched upon, and the conclusion is reached that a cardiopath going to a high altitude will incur no special risk if he will remain inactive until he becomes accustomed to his changed surroundings and his circulation has readjusted itself.

**The Cause and Specific Treatment of Hay-fever: A Preliminary Report on the Use of the Toxins and Antitoxins of Professor Dunbar.**—Emil Mayer made use of the material sent him by Dunbar on cases both of the spring and of the autumnal variety of hay-fever, in each instance employing a non-susceptible person as a control. One drop of the serum is capable of neutralizing the effect of twenty drops of the toxin solution. He observed the same reactions as have been described by Dunbar and others. The autumnal cases absolutely failed to react, but those of the spring variety reacted so satisfactorily to the antitoxin as to practically demonstrate the identity of the spring variety of hay-fever in this country and in Germany. Dunbar believes that the autumnal cases will be found to respond to some other toxin. The antitoxin serum is instilled into the eye or into the nose, as hypodermic injections have caused great local irritation.

**The Psychical Relations of Tuberculosis in Fact and Fiction.**—G. A. de S. Saxe summarizes his paper as follows: (1) The average consumptive exhibits traits of mind and temperament that are directly connected with the disease, although not specifically characteristic of it, and these have not received from medical men the attention they deserve (2) The only probable theory for the mental and moral degeneration of the consumptive is that of toxic poisoning of the central nervous system by the products of the tubercle bacilli. (3) The fundamental factors in the psychical make-up of the typical consumptive are the loss of self-control, the rise of brute selfishness. The increase of susceptibility to suggestion, emotion and nervous irritation, and the tendency to rapid nervous and psychical fatigue. (4) There is no tangible proof that the sexual functions are exalted in tuberculosis, but in all probability the sexual irritability is raised in the early stages of the disease and lowered coincidentally with the waning vitality in the later stages. (5) Any form of insanity may be found in tuberculous persons, the tuberculous toxin, along with other factors, contributing to mental derangement in susceptible individuals. (6) The criminal tendencies of consumptives have been observed with sufficient frequency to justify an investigation into the medico-legal question of restricting the responsibility of a criminal on the ground that he is tuberculous. (7) The euthanasia of consumptives is to be explained on purely physical grounds, the changes in the nervous system being so marked at the time of approaching dissolution as to efface the patient's suffering and render death easy.

*American Medicine, August* 8, 1903.
